If we have any criticism to make of the present work, it is that it conforms too closely to nature for the use of the student. Undoubtedly in nature one form of insanity merges into another, and all manifold groups, which have been separated by specialists, are, in real life, dovetailed into a composite entity. For the purposes of the student, the arbitrary groups are, however, necessary for him, and they should be drawn clearly and sharply. After, but not before, the knowledge of these types has been acquired, the dovetailing and interweaving processes may take place in the mind of the student. A wider knowledge of literature on the part of the author would, perhaps, have saved some mistakes. Thus, we read, page 193, that the patella reflex in general paralysis of the insane is at first exaggerated, afterwards dull, and finally absent, and on page 205, locomotor ataxia is not likely to be confounded with general paralysis of the insane. Now, the truth is, that locomotor ataxia is exceedingly frequent in general paralysis, and that it sometimes precedes and sometimes follows the development of the cerebral disease. Moreover, not rarely, instead of the sclerotic change attacking the posterior columns, it attacks the lateral portions of the cord, and the condition of the patella reflex depends upon the condition of the spinal cord, and is entirely independent of the brain-changes.

In dismissing this book, we want to again say that we consider it an extremely valuable practical work for those under whose charge the insane are brought.

VON ZIEMSEN'S HANDBOOK OF GENERAL THERAPEUTICS. Vol. IV.

New York: Wm. Wood & Co., 1886.

The fourth volume of this seven-volumed handbook is devoted to a discussion of the treatment of disease by climate and to general balneotherapeutics, the first part being written by Dr. Hermann Weber, the second by Prof. Otto Leichenstern. The same general characteristics that have distinguished the previous volumes are present in the one before us,—great attention to minutiae, great striving after scientific results, with a practical result hardly commensurate with the amount of labor. The knowledge of German literature displayed is very great, but the reader would be led to think that, outside of German, neither the science nor the art of medicine existed. For the well-trained American practitioner, who will read with discretion and care, much of value exists in the volume, but for those who desire an absolute guide the present book leaves still an hiatus, especially in regard to balneotherapeutics. Not only is there nothing whatever in regard to our American springs and baths, but very little virtue seems to be attached to any bubbling water that is not heavily impregnated with the joys of the Fatherland.

LECTURES ON THE DISEASES OF THE NOSE AND THROAT. DELIVERED DURING THE SPRING SESSION OF JEFFERSON MEDICAL COLLEGE. By Chas. E. Sajous, M.D., Lecturer on Rhinology in Spring Course at Jefferson Medical College, etc.

Philadelphia: F. A. Davis, Att'y, Publisher, 1885.

Dr. Sajous has given the medical world a carefully written, excellently illustrated work upon the subject of Diseases of the Nose and Throat; in fact, the illustrations are of unusual value, and are introduced with the utmost profusion. One hundred chromo-lithographs from oil-paintings by the author, and ninety-three engravings on wood, are given away with each volume. The author's experience is wide, being drawn not only from private practice as a specialist, but still more extensively from his connection with one of the largest special clinics in Philadelphia. He has aimed at interesting the general practitioner, his style being easy, clear, and free from too much technicality, and we readily see that the book will prove attractive to many who do not pursue special practice. The book illustrates well the fact that there exists a germ of decay in the apparently flourishing body of specialism, and the years will be few before we see all general practitioners of average capacity the possessors of

equal knowledge in all branches with the specialists of to-day. While aiming at little originality, the author claims to give to his work the results of "testing the therapeutic value of new methods." And we find at least two new things,—the new names which he has bestowed upon post-nasal catarrh, now "posterior nasal pharyngitis," and hay-fever, which appears as "periodical hyperæsthetic rhinitis." This latter name is so simple, fluent, and mellifluous that the public may actually clamor to have it, and it seems to us an exceedingly ingenious thing, when there is nothing new left to be done for the miserable old disorder, this giving it a new name and treating it all over again. Concerning the former disease, the author remarks, "The almost universal prevalence of post-nasal catarrh in this country has given rise to much speculation among specialists." The author, from want of space, will only state those views as to causation which he has personally entertained for some time. He then goes on to tell us about "chronic inflammatory processes in the neighboring parts," hypertrophic polypi and other growths, ignoring entirely the great question of whether the human nose was originally framed rapidly by its Creator, or slowly by evolution, strong enough to endure the peculiarities of our American climate, whether we as a race, rather mixed to be sure, are able to endure it, or whether any other race is better fitted. He fails also to investigate the burning question as to whether the American Indian had or has post-nasal catarrh, or hay-fever either. Has the noble savage ever been observed in a frequent use of the pocket-handkerchief, or in those substitutes for it somewhat in vogue among our imported citizens? Certainly he has had free access to climate and to pollen for centuries. Now, all these questions lead up to what we consider a rational treatment,—protect from the rough climatic changes, or raise the standard of the individual to meet them; but the nasal specialist prefers rather to abolish partially the nasal organ. Why not snip it off in the newly-born? Circumcise the nose as it were, uniting the raw edges with neat sutures, carbolyzed silk-worm gut preferred. Or, in the yielding state of the infantile bones, obliterate by pressure the nasal cavities. Perhaps, better still, permanent silver tubes, self-retaining, might be passed in either nostril, and compression then used. True, the senses of smell and taste would be destroyed; but smell is often offended, and taste there is no rule for. By

these tubes the air would be conveyed to the lungs without impinging upon the too sensitive nasal membranes, and, if not sufficiently warmed, small wire diaphragms might be fitted to the outer end of the tubes. The beauty of another nose would no longer excite envy; no noses would be broken or bitten off in the exercise of angry passions; following one's nose, which so often leads one in devious ways, would be impossible, and the terms Roman, aquiline, Grecian, and, best of all, the derisive word "pug" would fall into oblivion. The nose no longer being used, a few generations would direct the unused developmental energies of the economy to other parts,—brain perhaps, ears probably. No longer would our nasal tone be commented on so freely by the inhabitants of Britain, pocket-handkerchiefs could be abandoned, and bronchial catarrhs might also disappear when they attempted to begin in the head and were foiled. The remedy snuffine, so dangerous to mention, would not be mentioned for obvious reasons, and the nasal specialists, rested and refreshed, could organize invasion into the territories of the oculist and the aurist.

Among the many topics treated of by the author we find a chapter on epistaxis. This contains a valuable summary of the treatment of this at times very obstinate condition. The author recommends packing the anterior nares in obstinate cases, when the bleeding-point is sufficiently anterior. This is sometimes difficult to determine. The mere appearance of blood at the posterior nares, when the head is erect, by no means indicates that the source of the trouble is posterior; in fact, in the absence of definite information, packing the anterior nares should always be tried before plugging the posterior, an operation by no means easy, and at times, from constitutional causes, impossible. The pledgets employed are tied on a strong silk thread at frequent intervals, and the author recommends saturating them with styptics in solution before application; but plain absorbent cotton, smeared with vaseline to promote easy application, is much more readily used; in fact, the nostrils are packed for the sake of the pressure exerted.

In discussing the treatment of chronic post-nasal catarrh, the author says (page 229), "Agents which are partly eliminated through the glands of the nose and throat, when taken internally, are sometimes very serviceable." Cubebs is the principal remedy he has in mind, and ammonia with ipecac. We would suggest

eucalyptus, which has proved serviceable in many obstinate cases, as worth a further trial; and among local applications tinct. benzoini comp. of the Pharmacopœia.

In chronic and follicular pharyngitis, among the many local applications recommended, we look in vain for ergot, which, locally applied, alone or in combination with glycerin, possesses the same power as elsewhere, of constricting the dilated vessels. A few days' employment will often cause a visible diminution of their enlargement, and a simultaneous relief of the annoying dryness. The author describes membranous pharyngitis, and among its synonyms gives "aphthous sore throat," "croupous pharyngitis," and "herpes pharyngis." We think the latter synonyme an error, for, following the author's description closely, we find him enumerating among its causes "exposure to the influences of infectious matter, or close contact with persons suffering from diphtheria, scarlatina, etc." Our objection is a double one. There may be a special separate disease, "membranous sore throat," but if so, it is not caused by exposure to scarlatina and diphtheria. Else, in all human probability, it is but modified diphtheria, and can give the contagion to others; in fact, the profession is at present, thanks to the laws for the compulsory notification of infectious diseases, engaged in dodging the whole question. Adults are seldom attacked with severe diphtheria. They generally have the so-called diphtheritic sore throat; in fact, about what Dr. Sajous terms membranous pharyngitis. But the fashion of the day is to ignore light cases of diphtheria. Of all diseases it alone presents, according to most authorities, no light cases. Its mortality is high. In order to have it a child must either die or barely escape with its life; but the adult, with his simple patchy sore throat, is, in our opinion, in most cases, the disseminator of the poison which strikes so mysteriously. The second objection we make to the author's synonyms is in "herpes pharyngis" being named as equivalent to the condition under consideration, for there is a true herpes of the throat, seldom seen, we grant, but really existent, characterized by the same peculiarities as herpetic affections elsewhere, vesiculated in clusters, or in line of clusters, traversing the pillars, the soft palate, and the posterior pharynx, and it presents no points of similarity with the description of Dr. Sajous. It is caused by inhaling very sharp, dry, cold air through the open mouth, and, except the local pain, presents no great constitutional disturbance.

Taken as a whole, the volume of Dr. Sajous, however, will prove very useful, though we warn the beginner not to expect always to find the peculiar florid mucous membranes depicted in the author's chromos. The chapter on tracheotomy, towards the end of the book, gives us an illustration of the author's scale for tracheotomy tubes. For use in cases from six months old to twenty years he advises oral tubes, and has given a very excellent chapter on the subject.

E. W. W.

HANDBOOK OF PRACTICAL MEDICINE. By Dr. Hermann Eichhorst, Professor of Special Pathology and Therapeutics, and Director of the University Medical Clinic in Zurich. *Volume I. DISEASES OF THE CIRCULATORY AND RESPIRATORY APPARATUS.* One Hundred and Three Wood Engravings.

New York: William Wood & Company. 1886.

This is a somewhat elaborate handbook, and is a work of a high order, notwithstanding its modest title. Beginning, *in medias res*, with diseases of the circulatory apparatus, it is at once practical and concise. There is no waste of words in rewriting the well-worn introductions, but the subjects are handled in the most practical and thorough manner at once. Throughout this section special attention has been given to the illustration of sphygmographic tracings. The section includes diseases of the pericardium, heart-muscle, endocardium, neurosis of the heart, and diseases of aorta; diseases of larynx specially illustrated; of the bronchi, lungs, pleura, and mediastinum complete the volume. The chapter on the endocardium is one of the most able. The study of malignant endocarditis which the author gives is very thorough and complete. He considers the bacterial origin of this disease as fully established. Though generally traceable to wounds and septic poisoning through them, as in operations, injuries, puerperal fever, etc., it follows acute infectious diseases also, and at times "no cause can be demonstrated." Old rheumatic joint and endocarditic changes are often found previously existent. The pathological changes are minutely described, with the researches up to date into the bacterial problem.

The author says, p. 73, "The symptoms are extremely manifold." "In other cases the causes of the pericarditis are so prominent that the latter remains hidden," and "we may boldly maintain that no two cases are entirely alike." "In the typhoid form, days and even weeks may elapse before the diagnosis is decided, in other cases the diagnosis

of typhoid fever, which had been made with certainty, is suddenly overthrown on account of new developments, and changed to septic endocarditis," while previously we read, "In some cases death occurs in a few hours or days."

P. 75: "The differential diagnosis between intermittent fever and septic endocarditis may be undecided for a long time," and "as a rule the disease is recognized with great difficulty." "Special weight must be attached to embolic processes which are susceptible of external examination," as retinal hemorrhages in the diagnosis from typhoid fever. As for treatment, support strength, combat inflammation, prevent the detachment of emboli, and destroy the bacteria. To do the last mentioned the author advises salicylic acid and its compounds, large doses of alcohol or quinine, corrosive sublimate claiming some apparent successes, benzoic acid and benzoic acid, which deserve some trial; resorcin, which is doubtful and probably dangerous; ice-bags over the heart, and where the pulse is rapid digitalis and nitrate of potassium.

The chapter on "Neurosis of the Heart" embraces nervous palpitation, nervous cardiac pain, Basedow's disease, and intermittence of the heart. In the treatment of angina, ice-bags to the cardiac region are mentioned as sometimes useful, and sometimes "they do not act well." Hypodermic morphine is surprisingly and rapidly beneficial, but not devoid of danger, nor are chloroform or ether inhalations safe. Amyl nitrite "will only be useful" when there is "coolness, pallor, or a livid color of the skin." The recently-advised use of potassium iodide is not mentioned by the author.

In the chapter on "Diseases of the Bronchi" there is given an appendix on diseases of the tracheo-bronchial lymphatic glands. Acute inflammatory enlargement of these glands, the author tells us, is an almost constant concomitant of acute inflammation of the air-passages. Rupture of these glands "is evidently not a frequent cause of death," though their suppuration, rupture, and discharge is very common.

The chapter on "Hæmoptysis" is rich in diagnostic suggestion. The chapter on "Alveolar Emphysema of the Lungs" contains, among other illustrations, one of a pneumatic cabinet. The two figures, presumably medical, seated in its spacious interior, are engaged, the one in reading the other in meditation. As the air became rarefied their positions probably change to others more active

and earnest, though less dignified and graceful. Throughout the work the illustrations are apt and instructive, and as far as the first volume goes it promises us an exceedingly useful and thorough work on the subject of practical medicine.

E. W. W.

SEVENTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF ILLINOIS, with an Appendix, 1885.  
Reprint of National Board of Health. 1885.

The expectation of cholera has given State and National Boards of Health a large and comparatively inexhaustible topic, and enabled hundreds of local sanitary authorities to rewrite and publish at public expense the threadbare history of the disease. On paper, how hard they have striven to protect us! Off paper, perhaps from no fault of their own, how little they have done! The very paper on which they print their protests against the importation of infected rags has probably been made from infected rags admitted, with the thorough disinfection which a few mild protests and a square back-down always give. The National Board's Report gives us a summary of the sanitary legislation throughout the United States, and in the Appendix a table of the mortality in cities and towns of the United States for 1884, beginning with Bath and ending with San Francisco.

The Illinois Report is mostly made up of tables of vital statistics; contains a list at the end of the medical colleges of the United States and Canada from 1765 to 1885, which may prove useful for reference; gives us any amount of cholera literature, and decisions under medical practice laws throughout the United States.

E. W. W.

CLIMATOLOGY AND MINERAL WATERS OF THE UNITED STATES. By A. N. Bell, M.D., editor of the *Sanitarian*, etc.

New York: William Wood & Co., 1885.

To know our own range of climate thoroughly is to take the first step to its proper use. To do this we must have a clear understanding of the varied conditions which are met with over a very extensive territory, ranging in extremes from tropic to polar. A good guide to the varieties of weather likely to be experienced at any given time in the year, in any given place, is invaluable, when sending our patients in quest of a healthier or more suitable atmosphere than their own locality affords. The probable amount of rainfall, the extreme variation of the thermometer, the dryness and the moisture at given seasons, the general features of the

country, nature of the soil and the geological formations underlying it, and the nature of its waters, all these are necessary knowledge to-day.

The matter of mineral springs alone is very important. To have in one handy volume an analysis of every native spring whose waters have become prominent in the treatment of disease is by no means a small matter, and Dr. Bell has done the medical world a great service in collecting the varied and useful information on these subjects which we find in the volume before us. As a book of reference it will often prove exceedingly valuable.

E. W. W.

DICTIONARY OF PRACTICAL SURGERY. By various British Hospital Surgeons. Edited by Christopher Heath, F.R.C.S., etc.

Philadelphia: J. B. Lippincott Company, 1886.

Full without prolixity, written by experienced writers whose very names claim respect, recent as possible, compact and legible, these are the requirements of a good dictionary of technical science, and the one before us answers the conditions well. As we turn its clearly-printed pages we see appended to the articles well-known names,—names of men especially fitted by experience and special study for their allotted work. We find nothing slighted. Extensive articles where needed. Much condensed in small space where possible. An investigation of special topics leads us to believe that the editor has been fully alive to the necessity of securing recent and fresh work, fully up to the busy times in which we live, when too often the carefully-wrought work of to-day is eclipsed by the work of to-morrow.

As a dictionary of surgery the editor has taken a broad view of his work, and has made the field as wide as possible. We notice many articles of interest which occupy the debatable ground between surgery and medicine. Gynecology has not been slighted, nor eye-, ear-, and skin-diseases. The arrangements for ready reference, the cross-references, the headings, are all as complete as could be desired.

Among the many contributors the eye strikes the names of Felix Semon, Christopher Heath, Watson Cheyne, J. Warrington Haward, William Stokes, Henry Power, Robert Liveing, G. V. Poore, Victor Horseley, Sampson Gamgee, R. J. Goodlee, J. Knowlsby Thornton, Henry F. Chavasse, Brudenell Carter, Stephen Mackenzie, Thomas Smith, Jonathan Hutchinson, Bernard Roth, and a host

of other names mostly familiar to the reading man, and giving him confidence in the reliability and authoritative character of the book. And we can cordially recommend it to all who need a Dictionary of Surgery.

E. W. W.

A MANUAL OF DISEASES OF THE SKIN. By Balmanno Squire, M.B. Lond.

Chicago: A. N. Marquis & Co., 1886.

To relate fully but briefly what is known at present respecting diseases of the skin is the author's aim in this work. Of such moderate dimensions is it that it can readily be carried in the pocket. It affords one an opportunity to familiarize oneself with the most recent views and practice in skin-affections, using the book at odd moments, and yet finding that with all its condensation it is by no means a bare outline of the subject. The author omits eruptive diseases and cancer, and insists on the great primary necessity of an accurate diagnosis. Yet he admits that the "imperfect state of cutaneous pathology throughout Europe" leaves diagnosis in an unsatisfactory state. Blind reliance in the efficacy of specifics is deprecated, and he says, "We have now better means at our command than a course of arsenic, sarsaparilla, or dulcamara." He does not deny that arsenic has its value, but speaks of it as the specific that has fallen most. Throughout the book the author will be found drawing largely on his own experience, and disposed to discard this and that mode of treatment on the ground of its inutility in his hands. The therapeutics of the book, as judged from a rapid perusal, are sound, and the hygienic recommendations made with great care and minuteness, and many practitioners, we venture to think, would be much wiser for a thorough reading of its pages.

### *WAS IT CANTHARIDES-POISONING?*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I was called to see Mrs. B., a spare, nervous woman of about 45, at noon on Saturday, September 5, 1885. She was in stupor, extremities cold, pulse about 120, and very weak, with mild tetanic spasms every five minutes. Respiration seemed normal; the pupils were equal and normal.

The only history I could get at the time

was that her family found her about 10.30 A.M. sitting in her chair, partly stupefied, and complaining incoherently of being sick.

They got her into bed, where she grew rapidly worse while they were waiting for a doctor. She became, so they said, pulseless and extremely cold, so they thought death imminent. At last they began giving brandy in small and frequent doses, and considerable improvement in pulse and temperature had, they said, resulted before my arrival.

After several doses, about 15 drops each, of aromatic spirits of ammonia, at fifteen-minute intervals, and a hot mustard foot-bath, I succeeded in rousing her so as to answer questions. She complained, however, of nothing but pain in the back upon movement.

As all the prominent symptoms had improved, I ordered the stimulant to be continued in diminished doses every half-hour, while I went to my dinner.

Returning at 2 P.M., I found her sleeping naturally, and her pulse and temperature nearly or quite normal. She had in my absence developed a new symptom, strangury, and had passed, with considerable straining and pain, two stools, together about half a coffeecupful, of mucus mixed with blood.

She had returned to perfect consciousness before falling asleep.

Without awaking her, I left a mixture of opium and ergot, in pretty full doses, to be given when she awoke, and repeated frequently, if necessary, and called again at six o'clock.

At this time she was "as well as ever, except a little tired." She gave this account: In the morning she had felt unusually well, had eaten a hearty breakfast, partaking only of the same dishes as the rest of the family.

At about 10 A.M., while visiting a neighbor, she began to feel an indescribable sensation "in her stomach," not nausea, nor real pain, but a queer feeling, entirely new to her.

In her walk home her head began to swim, her fingers and toes to tingle, and "every drop of blood in her body just boiled." She had a desire to go to the privy, but was afraid to do so lest she should become worse there, and not be found by her family. She had no vomiting at any time. She insists, in spite of her husband's ridicule, that just before she lost consciousness her fingers "turned perfectly black as far up as the second joint."

She had had since childhood no previous illness except sciatica. For this she applied a blister, three by four inches, to the hip on Tuesday, the 1st of September, leaving it in

place twelve or fourteen hours. On Thursday, having pain in the knee, she reapplied the same blister to the calf of the leg, and removed it after about eight hours. In both applications the pain was relieved, but she noticed no other effect, except that the Thursday blister "filled up with yellow corruption" instead of water, as on Tuesday.

Now, the query is, Was this a case of cantharides-poisoning? If not, what was it? If she was poisoned by absorption from the blister, why were the symptoms delayed from Thursday evening to Saturday noon, at least thirty-six hours after its final removal?

Excepting some neuralgic pains, she has been in good health since that time, now over six months ago.

I would be glad to have any of the readers of the GAZETTE enlighten me as to the nature of the above case.

Very respectfully yours,

E. H. BIDWELL, M.D.

VINELAND, N. J.

#### *HEMICRANIA TREATED BY FLUID EXTRACT OF TONGA.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN,—I usually have two to three cases of hemicrania every year in my practice, and heretofore I have had no trouble in curing all my cases either with large doses of sulphate of quinine, or other remedies used in such cases, such as bromides of potassium, sodium, or ammonium, gelsemium, sulphate of nickel, croton-chloral, or morphine, as seemed specifically indicated.

But recently I treated a severe case, in a young woman aged 26, of two months' standing, during which time I gave alternately all of the above remedies a fair trial, though none seemed to do any good. She was free from pain only while under the influence of hypodermic injection of morphine.

This being rather a severe case, perhaps I had better give the leading symptoms, as then a proper diagnosis can be made. The pain commenced gradually in the right half of the head, but in a few days the paroxysms became very painful, accompanied with slow circulation, cold skin, oculo-pupillary and caloric disturbance. During a severe paroxysm the pain, as the patient expressed it, was of a constricting character, covering the entire right side of the head, which would be increased by pressure. There was more or less nausea and vomiting; appetite indifferent. During a severe paroxysm there were hallu-

cinations present, the patient hearing noises in the ear, seeing sparks of fire, wanting to go somewhere, or expecting some one to come. During the remissions she would feel nearly free from pain, as long as she was quiet. The secretions and excretions were normal. No organic disease in any part of the system.

After having used all the leading remedies, I picked up a copy of the *THERAPEUTIC GAZETTE*, in which I noticed a number of such cases treated by the fluid extract of tonga. Having it in my office, I prescribed in 30 minim doses every three hours, giving three doses of the tonga every twenty-four hours.

The patient took nine doses, which effected a radical cure, and recovered rapidly. I report this severe case for the benefit of others.

JOHN A. HENNING, M.D.

GARNETT, KANSAS.

### Notes and Queries.

---

#### *BUISSON'S TREATMENT OF HYDROPHOBIA.*

Centres have been established in various parts of London and in a few provincial towns for carrying out M. Buisson's treatment of hydrophobia. The wound is washed with a solution of ammonia; the patient has a daily vapor-bath at a temperature of 42° to 48° Réaumur, with a view to producing profuse perspiration for seven consecutive days, and draughts of a hot infusion of borage, also with a view to promoting the diaphoresis. Dr. Buisson is said to have cured himself after the development of the symptoms of hydrophobia. He and his disciples regard the method as an infallible preventive of hydrophobia, and as an equally certain cure, if begun on the first day of the developing disease; on the second day its effect is less certain, and later it has no effect in staying the course of the malady. As to the merits of the treatment we can assert nothing. It is alleged to have prevented or to have cured the disease a hundred times. But the sources of fallacy are innumerable. We do not yet know the proportion of individuals bitten by a mad dog who become the subjects of hydrophobia. It is difficult to conceive that profound sweating can stay the course of a disease which seems to be due to the development of a living germ in the medulla oblongata. That washing a recent wound with liquid ammonia and making the individual perspire profusely should be able to prevent the disease can be reasonably conceived.—*Lancet*, April 3, 1886.

#### *THERAPEUTICS OF TRICHINOSIS.*

The value of glycerin in the treatment of trichinosis has been repeatedly alluded to in the *GAZETTE*. FIEDLER noticed several years ago, in the preparation of microscopic specimens, that trichinæ and their embryos died at once when brought in contact with glycerin (even if diluted with two to three times its quantity of water). This was evidently the result of the hygroscopic power of glycerin, causing the abstraction of water from the parasites. This fact led Fiedler to treat animals, fed purposely with trichinous meat, with glycerin, but he did not obtain any positive results. Later he exhibited glycerin in several cases of trichinosis in man, and was successful. Mercel also published a case of trichinosis cured by glycerin, so that the profession regards this drug justly indicated in this affection.

In the *Deutsches Archiv für Klinische Medizin*, vol. xxxvii. No. 12, Fiedler recommends the hourly administration of a tablespoonful of pure glycerin in trichinosis, though only in graver cases, as large doses of the drug may produce hæmoglobinuria and other toxic symptoms.

In this instance the employment of Unna's keratine pills, or keratine capsules, which dissolve only in the small intestines, would appear very appropriate. To complete the abstraction of water from the parasites, Fiedler advises to give large doses of alcohol and to prescribe a rigid dry diet. Glycerin may also be injected into the rectum. A powerful purge, though, is to precede all these therapeutic measures.

---

#### *THE USE OF LANOLIN IN OINTMENTS.*

At the meeting of the College of Physicians of Philadelphia, held April 7, 1886, DR. THOS. G. MORTON (*Med. News*, May 8, 1886) made some remarks on lanolin, and exhibited a few specimens of this preparation from the wool of sheep. Those who have used it have been much pleased with its employment in the preparation of ointments for external application. It can be readily rubbed into the skin and produces no irritation, and, therefore, would probably be valuable in massage. It is probable that substances combined with lanolin will be more readily absorbed than if prepared with other bases.

One of the remarkable properties of lanolin is that it can be readily combined with water. It takes up more than its own weight of water. Unna states that cooling ointments should

contain large quantities of water. Dieterich, with a view to determining the quantity of water taken up by different salve bases, experimented with twenty-one different bases at a temperature of  $15^{\circ}$  C., taking for each experiment 100 parts of the base. His results were as follows: Cosmoline took up 4 parts of water; lard, 15; benzoinated lard, 17; and lanolin, 105.

Lanolin, as it now appears in the market, is a perfectly neutral base, and hence is not apt to decompose any medicament which may be added. Lassar experimented with it on four hundred patients, and states that lanolin is readily absorbed by the skin, does not produce any irritation, and permeates the lower layers. Bachmann rubbed a ten per cent. iodide of potassium ointment, made with lanolin, into the skin for five minutes. After the lapse of half or three-quarters of an hour, iodine was detected in the urine. The elimination of the iodine by the urine continued for fourteen days after several applications of the ointment. Lanolin was used by the ancients, and is mentioned by Ovid, Herodotus, Plinius, and Aristophanes.

Liebreich patented his process in the United States in January, 1883, and it is concisely stated as follows:

"He takes the suds from the washing of wool in the mill, submits it to the action of a centrifugal machine which separates the soapy, oily suds from the dirt associated therewith, decomposes the suds by an acid, whereby the acid and the saponifying alkali unite and the saponified wool-fat is separated, combined with about one hundred per cent. of water; this is then thoroughly washed with cold water, then heated so as to separate the water and the wool-fat, and again combined with a definite proportion of water, and lanolin is the result.

"Or, he treats wool with alkaline water, producing his suds in that way, and then proceeding as already outlined.

"A much quicker and less complex way of making the article is to treat the wool directly with petroleum benzine; distil off the benzine, and the wool-fat remains; combine this with a proper proportion of water, and lanolin results. In his patent specifications, Liebreich speaks of this process, but says it is objectionable because of the difficulty of getting rid of the benzine odor.

"Merino wool, clipped without the sheep being washed, contains, it is said, the enormous proportion of sixty per cent. of this fat.

"When it is considered that all wool aver-

ages about forty-five per cent. of its weight of this fat, that it has all to be removed before the wool can be manufactured into fabrics, that up to this time it has had no value, that the process for its extraction is not a very expensive one, and that lanolin is thirty per cent. water, it appears reasonable that lanolin will certainly be as cheap as lard as soon as competition in methods of extraction and in supplying have an opportunity to affect its price."

Dr. Keen remarked that he had used lanolin in several instances during the last week or ten days. One case was that of a child, 8 years of age, with an enlarged gland under the jaw, the size of an English walnut. He prescribed iodine, 2 grains to the drachm of lanolin. He saw the child a week ago, and the swelling had almost entirely disappeared. This was a more rapid disappearance than he had ever seen from other iodine applications. This is the only case in which he had any results, although he had used it in a number of instances, and liked it very well.

#### FOOD PRESERVATIVES.

An interesting paper was recently read by MESSRS. SULMAN and BERRY before the Chemical and Physical Society of University College; it was important also from its practical bearings on the preservation of foods, and especially milk. Their investigation, limited to the boracic, salicylic, and benzoic compounds, proved that such substances as asepsin, glacialine, and boroglyceride owed their preservative qualities almost exclusively to the free acid contained in them. Boroglyceride contained twenty-five per cent. of the genuine boracic ether of glycerin, and seventy-five per cent. of free acid and glycerin in equivalent proportions. The true compound, the ice-like solid, is immediately resolved into free acid and glycerin by the addition of water, and this reaction probably takes place when the true compound comes into contact with aqueous liquid or animal tissue. We agree with the authors of the paper that the use of so much free boracic acid is undesirable and injurious, especially as a preservative of milk for children. Salicylic acid and salicylates are not substances that can be used with impunity, and as they appear to be useless as preservative agents, their rejection is doubly necessary. Again, benzoic acid precipitates the casein of milk. The best agent appears to be benzoate of sodium, which is tasteless when pure, is one-third more power-

ful than boracic acid, and innocuous when taken in small quantities for prolonged periods. —*Lancet*, April 10, 1886.

#### ON SAPONIMENTS.

The chemical factory of Dietrich, in Helfenberg, near Dresden, has, as we have learned, brought recently into the market a line of new preparations called saponiments, or medicinal opodeldocs, which are intended to compete especially with the medicinal soaps. As the base of these saponiments Dietrich uses neutral oil and stearine soaps prepared by dialysis. These soaps are dissolved in acetic acid and incorporated with such medicinal substances as are mostly used in the dermatological practice. The saponiments can be prepared in the shortest time, and in the smallest quantity,—are more constant than soaps, and contain the active principles in a more concentrated manner than these. In acute inflammatory diseases of the skin the saponiments cannot be employed: their proper place is in chronic, squamous, pruriginous, and parasitic dermatoses, in acne, ichthyosis, and especially in the affections of the hairy skin.

#### THE METRIC SYSTEM.

We have always made it a rule in making our abstracts of papers from foreign journals to convert the metric system into apothecary's measure: sometimes we have overlooked this, and to facilitate this conversion in the future, we call attention to the following rules published by DR. OTTO A. WALL in the *National Druggist*, May 7, 1886. Dr. Wall claims that rules for converting grains into grammes or *vice versa* with mathematical exactness are superfluous under all ordinary circumstances; for when exactness is really desirable, it can be better secured by referring to tables of equivalent quantities, and when it is not necessary, these rules are too cumbersome and tedious for practical use.

#### Equivalents of Fluid Measure.

15 minims	= about 1 cubic centimetre.
1 fluidrachm	= about 4 cubic centimetres.
1 fluidounce	= about 30 cubic centimetres.
1 pint	= about 0.5 litre, or 500 cubic centimetres.
1 quart	= about 1 litre, or 1000 cubic centimetres.

#### Equivalents of Weights.

1 grain	= about 0.06 gramme, or 6 centigrammes.
15 grains	= about 1 gramme.
1 drachm	= about 4 grammes.
1 troy ounce	= about 30 grammes.

For use in constructing a metric prescription, it becomes necessary to adopt some easy rules for conversion from apothecary's to metric weights. The simplest method is as follows:

*Multiply ounces by 30 to get the number of grammes. Multiply drachms by 4 to get the number of grammes.* When there are less than 60 grains, divide by 15 to ascertain the number of grammes. If there is a remainder, or if the number of grains is less than 16, we may reduce to fractions of a gramme, as follows:

*Assume the gramme (written 1.00 Gm.) to be equal to 15 or 16 grains. To convert any number of grains less than 16 into centigrammes, think what fraction that number is of 15 or 16, as may be most convenient, and then take that fractional part of 1.00 gramme to express the metric equivalent, ignoring fractions beyond the second decimal place.*

The following will make this clear:

1 grain	= $\frac{1}{16}$ of 16 grains; $\frac{1}{16}$ of 1.00 gramme = 0.06 gramme.
2 grains	= $\frac{2}{16}$ of 16 grains; $\frac{2}{16}$ of 1.00 gramme = 0.12 gramme.
3 grains	= $\frac{3}{16}$ of 16 grains; $\frac{3}{16}$ of 1.00 gramme = 0.20 gramme.
4 grains	= $\frac{4}{16}$ of 16 grains; $\frac{4}{16}$ of 1.00 gramme = 0.25 gramme.
5 grains	= $\frac{5}{16}$ of 16 grains; $\frac{5}{16}$ of 1.00 gramme = 0.31 gramme.
6 grains	= $\frac{6}{16}$ of 16 grains; $\frac{6}{16}$ of 1.00 gramme = 0.40 gramme.
8 grains	= $\frac{8}{16}$ of 16 grains; $\frac{8}{16}$ of 1.00 gramme = 0.50 gramme.
9 grains	= $\frac{9}{16}$ of 16 grains; $\frac{9}{16}$ of 1.00 gramme = 0.60 gramme.
10 grains	= $\frac{10}{16}$ of 16 grains; $\frac{10}{16}$ of 1.00 gramme = 0.66 gramme.
12 grains	= $\frac{12}{16}$ of 16 grains; $\frac{12}{16}$ of 1.00 gramme = 0.75 gramme.

Or we remember that a grain equals 0.06 gramme, and multiply this by the total number of grains. For instance, 20 grains =  $20 \times 0.06$  gramme, or 1.20 grammes; 35 grains =  $35 \times 0.06$  gramme.

#### CASE OF RUPTURE OF THE LIVER IN WHICH PARACENTESIS WAS PERFORMED SUCCESSFULLY.

As recoveries from rupture of the abdominal viscera are extremely rare, the following case, which seems to be clearly of that nature, reported by MR. LOUIS FITZPATRICK in the *Australasian Med. Gaz.*, April, 1886, is of interest. The case was that of a man aged 26 years, by occupation a laborer, who was run over by a wagon loaded with heavy stones, supposed to weigh in all about two tons. The wheel of the wagon passed over the limb, and in its progress severely crushed the shoulder-joint, broke from four to six ribs, passed over the region of the liver, slightly fracturing the top of the crest of the ilium. When Mr. Fitzpatrick saw him, he was suffering great pain, and was in a state of collapse from shock, and all the first day suffered from very severe pains, which he de-

scribed as being like the cramps of cholera. These were relieved by opium. On the second day the abdominal pain became intense, the temperature rose, and the eyes and body jaundiced; the urine dark and fæces white. The patient also vomited large quantities of bile. On the third night the symptoms of traumatic peritonitis became very marked, and although opium and hot fomentations appeared to relieve the pain, the abdomen was considerably enlarging; at first it was tympanitic, but became entirely dull, bulged out at the flanks, and fluctuation could be distinctly felt on movement. Mr. Fitzpatrick concluded from these symptoms that there must be a rupture of the liver, with an escape of bile into the peritoneal cavity, and he therefore performed the operation of paracentesis six days after the accident. Eight quarts of a bilious fluid containing flakes of lymph were drawn off by the aspirator; he was then bound up with hot bandages and kept very quiet. The rent in his liver or gall-bladder, wherever it may have been, soon healed, as the jaundice began to fade and the bile to appear in the stools. The urine became healthy, the skin clear, and six weeks after the accident he left the hospital well.

In this case the rupture must almost certainly have been in the gall-bladder, but the fluid drawn off in the peritoneal cavity was almost entirely free from blood, and if the rent had been in the substance of the liver, which is a highly vascular organ, there must have been very considerable hemorrhage.

#### PROCESS FOR LANOLIN.

Lanolin, obtained from the alkaline water-washings of wool, is a fatty body consisting of varying proportions of cholesterin and fat-acids, with which is incorporated a certain percentage of water, which, becoming quickly absorbed, forms a smooth, white, homogeneous, unctuous mass. GAWALOVSKI proposes a new method for its preparation, as follows:

The wool-washings are first passed through a fine sieve to free them from mechanical impurities, and then through a convenient quantity of cut-straw or sawdust; the solution is then treated with magnesium sulphate, and the resulting magnesium soap, containing also the cholesterin, is collected, well washed with water, then drained and allowed to dry by exposure to air. It is then treated with sufficient diluted hydrochloric acid to decompose the soap; a large excess of hydrochloric acid should be avoided, but sufficient added

until a slight excess of acid is indicated, which is afterwards removed in the process. The resulting fatty scum, consisting of fatty acids and cholesterin, is drained and treated with petroleum benzine in a closed vessel, slightly warmed to about 85° F. to aid solution, and then filtered through flannel in a closed filter press. The petroleum benzine is then driven off by evaporation or distillation, and to remove any remaining traces of hydrochloric acid the residue is treated with from one-tenth to one-fourth per cent. of carbonate of magnesium, rubbed up with water, the mixture being then well washed with fresh portions of water until the water-washings are no longer milky from the presence of magnesium carbonate. It is again melted, filtered while hot through flannel, and, when cold, water is incorporated and the lanolin becomes white, hard, and smooth.—*Western Druggist*, May, 1886.

#### ACUTE ARTICULAR RHEUMATISM IN A MOTHER AND HER NEW-BORN CHILD.

DR. SCHAFER, of Pankow (Berlin), reports in the *Berliner Klinische Wochenschrift* of February 1, 1886, the following interesting case of a simultaneous rheumatic attack in a mother and her new-born child: Mrs. N., æt. 35, was seized a few days previous to her confinement with inflammatory rheumatism, attacking the left hip-joint and the right wrist. The child was born while the mother was still feverish, and fully under the influence of the rheumatic intoxication. Three days after birth a rheumatic swelling of both ankle-joints was noted in the child, together with a rise of temperature. Later the hip- and finger-joints became likewise affected, leaving no doubt as to the correct diagnosis. The child was treated with minute doses of salicylate of sodium, but without success; the medicine besides had to be soon discontinued on account of the gastric irritation it produced. After three to four weeks both mother and child improved.

There can be not the slightest doubt that we have to deal here with a case of acute articular rheumatism in a new-born child, contracted by infection from the mother in intra-uterine life. This case of infection is particularly interesting, as it tends to confirm the assumption, first pronounced by Edlefsen (Wiesbaden Congress), April, 1885, that rheumatism must be classed with the affections of an infectious nature. Neither in Henoch's

nor in Gerhardt's text-book on diseases of children can we find a single case of this kind reported, which is proof enough of its exceptional nature. In the *Lancet*, however (1882, p. 804), Ernest Pocock reports a case resembling very closely the one published by Schafer.

#### DANGEROUS ANTISEPTICS.

The value of an antiseptic is naturally proportionate to its influence as a destroyer of animal or vegetable life, but this is not the only test of its applicability in surgery and medicine. Some agents, though perfectly efficient as deodorizers or disinfectants, have been to a large extent superseded on account of their disagreeable smell, while others—and this is the class to which we wish to direct attention—have to be used with great care, on account of their liability to become absorbed and give rise to toxic symptoms. Three of the best-known and most popular antiseptics are included in this category, viz., carbolic acid, iodoform, and corrosive sublimate. All three are liable, when used as lotions or irrigations, to be absorbed and give rise to very distressing symptoms, and in some cases even to a fatal result. Corrosive sublimate is of comparative recent origin as an antiseptic, and is without doubt one of the most powerful agents at our command for this purpose. It is, however, like the others, liable to absorption, and owing to its intensely poisonous character the most untoward effects occasionally result from its use. In a recent number of the *Nouvelles Archives d'Obstétrique et de Gynécologie*, DR. LUCIEN BUTTE has taken the trouble to collect the notes of some twenty cases of puerperal diseases in which the employment of the *liquor de Van Swieten* (a 1000 solution of the perchloride) was attended with fatal results. From the rapidity with which fatal intoxication took place in most of the patients, the characteristic salivation and gingivitis were absent, and in several the cause of death was not suspected until revealed at the post-mortem examination, the abdominal pain and diarrhoea being attributed to puerperal causes. The symptoms generally presented themselves within from twenty-four to forty-eight hours, and rapidly led on to collapse. The effects were more marked in patients of a debilitated or cachectic constitution, and lacerations of the cervix or perineum or ulcerating surfaces seemed to favor absorption to a marked degree. With these facts before us, it becomes

desirable to use the perchloride of mercury with great caution, even in extremely dilute solutions, and especially to watch attentively for any indication of its absorption. The absence of some of the characteristic symptoms in those very cases where from the rapidity of its action it is particularly dangerous, together with the liability in puerperal cases of mistaking its symptoms for those incidental to the condition of the patient, render it a dangerous agent, notwithstanding its usefulness, and if an antiseptic can be found which will afford as satisfactory results apart from the risk of toxic effects, it would doubtless promptly take the place of the sublimate.—*Med. Press*, May 12, 1886.

#### FRANCISCEINE.

Francisceine, according to the *British and Colonial Druggist*, is proposed as the name of a new alkaloid which has just been extracted from the Brazilian manaca root, the produce of the *Franciscea uniflora* and certain other species. The principle in question has a very powerful purgative and diuretic action, and is also possessed of diaphoretic and emmenagogue properties.—*Lancet*, April 10, 1886.

#### THE USE OF LACTATED FOOD.

DR. J. MILNER FOTHERGILL writes concerning lactated food, which is said to consist of the purified gluten of wheat and oats, with barley diastase and malt extract combined with a special prepared milk-sugar.

Such a food can be added to milk. So prepared with milk it forms an admirable food for infants and dyspeptic persons who require very digestible aliments.

But it has a wider range of utility. The body-temperature is kept up by the combustion of grape-sugar. Grape-sugar is supplied from carbo-hydrates, either the insoluble starch or the soluble sugar. Starch forms a great portion of our food, and is converted into grape-sugar within the body. Where the system is unequal to the digestion of starch, as in feeble digestion or conditions of acute disease, then predigested starch must be furnished to the organism. Otherwise the system will perish of exhaustion, just as a fire dies out when its fuel is consumed.

Beef-tea contains nothing which can form grape-sugar, and, in fact, is a pleasant stimulating beverage or food adjunct, but without food value practically. (For what food value it has is so infinitesimal that it is not worth

counting.) But when it has added to it a food such as lactated food, it has a distinct measurable food value. Consequently, such food should be given with beef-tea, and the compound forms a valuable food.

When lactated food is placed in water hot enough to be sipped, a rapid transformation of the starch remaining in it (by the diastase it contains) goes on; and a nutritive fluid is the result which requires but a minimum of the digestive act.

Such fluid can be flavored and drank as a nutritive beverage, specially acceptable in febrile conditions. Flavored with lemon, ginger, cloves, or other flavoring agents, to give variety,—a matter far too much neglected in the treatment of the sick,—it can be largely used. Or wine, either red wine, as claret, or sherry or port, can be added to it when a little stimulant is required, and brandy when a stronger stimulant is indicated.

The resort to farinaceous matters, predigested, must become greater and greater as our knowledge of digestion and its derangements wax larger. It is not merely in the case of feeble infants that such predigested starch and milk-sugar are indicated and useful; persons of feeble digestion require these soluble carbo-hydrates, which they can assimilate.

But an equally great matter is the feeding of persons acutely sick, and especially where there is pyrexia, who now are allowed to perish of inanition on the mistaken conviction that beef-tea is a sustaining food. It is in the sick-room that soluble carbo-hydrates have a great future before them.

#### VICARIOUS MENSTRUATION.

The subject treated of in DR. BARNES'S able paper read before the British Gynæcological Society on the 14th ult., has always been one of great interest. The phenomena associated with it have not always been easy to accurately appraise, they have not been of frequent occurrence, and there have generally been present accompanying circumstances that have prevented the thorough and scientific study of them.

So much has this been the case that the condition itself has been doubted, and that by a no less keen and distinguished observer than Dr. Wilks. Perhaps a good deal of the obscurity would be removed by a clear definition of the term vicarious menstruation. If by this is meant the monthly discharge of a

*menstrual fluid*, we shall have to deny, with Dr. Wilks, that there is such a thing as vicarious menstruation; but if it is taken simply to mean a monthly discharge of blood taking the place of that from the uterus, many of our difficulties vanish. Dr. Barnes accepts the old definition,—*Menses per vias insolitas erumpentes; menstruatio vicaria*; as also the rendering by Leishman, "the menstrual molimen is relieved by a discharge through an unwonted channel." Dr. Barnes himself "proposed the term 'ectopic menstruation' to express the idea of menses escaping at the wrong place." We think the designation a happy one; but as yet it has to gain possession of the field. If in this definition we take the term menses to mean nothing more than a monthly flow of blood, vicarious menstruation becomes an entity about the existence of which there can be no doubt.

One of the factors in its production is increased vascular tension, manifested by turgescence of the capillary and venous system, and by the sphygmograph; the other is some obstacle to the flow of blood from the proper organ, as in the case of menstruation with absence of uterus. These cases of menstruation with absence of uterus are among the clearest cases of vicarious menstruation. Dr. Ave-ling seems to think not. *En passant*, we may remark that our author is a sturdy defender of the ovarian, or rather ovular, origin of menstruation.

An opportunity of generalizing is rarely neglected by Dr. Barnes, and in the present paper he acts up to this manner. To his mind menstruation is represented, in its various stages, in pregnancy, abortion, labor, and lactation. "These hemorrhages," he says, "have one characteristic in common. They are conservative in design and probably in effect." He might have generalized further, and we think it a pity he did not. He might have cast his eyes over what we are pleased to call the "lower" mammals. They do not menstruate, and thus have none of these "hemorrhages conservative in design and probably in effect," and as far as we can see they are none the worse for it. An explanation on this point is much needed. It is true that as a rule the females die early, but as a matter of fact so do the males, so that the want of conservative hemorrhages can scarcely be charged with their early doom. Leaving other classes of mammals out of the question, however, if they can with propriety be left out when they have almost everything else in common with ourselves, there really seems to be a good deal

of truth in the view he advances. "There is," he says, "a solidarity in the organism, binding the constituent organs with unity, and making them work with one consent." From this menstruation is not simply a function of the uterus and ovaries, but of the system, the due performance of which is necessary to the well-being of the individual. "If, then, menstruation is not carried out in the ordinary way . . . an attempt . . . will be made (1) by ectopic discharges of blood, (2) by discharge of mucous serum, (3) the material will be used up in other functions . . . (gestation, lactation), (4) building up new tissues . . . fat or other aberrant forms of metabolism, (5) effusions into the connective tissue, serous cavities, or in the substance of organs, (6) by exciting various neuroses." Among routes chosen for vicarious menstruation are the stomach (hæmatemesis), the nose (epistaxis), the skin ("a true bloody sweat," the bumps of erythema nodosum, ulcers, blood from sweat-glands, nipples), the conjunctiva, the intestines (diarrhœa and piles). All these forms are illustrated by numerous interesting cases.

His views are fairly, if not fully, summed up in his conclusions: "That as menstruation is a physiological necessity, so when the function cannot be performed in the ordinary way, some substitute for it must be found or mischief will ensue.

"Vicarious or supplementary functional action is a fundamental law in physiology.

"There is nothing exceptional in vicarious menstruation. Vicarious menstruation may occur under many phases. It is conservative in intent and action, lessening or averting evil."

In the discussion that took place on the paper there was very little diversity of opinion expressed. Drs. Bantock, Grigg, Ralfe, Heywood Smith, and Murphy all agreed that a discharge of blood occasionally takes place at more or less regular intervals from parts of the body other than the uterus, either along with menstruation or alternating with it, or in amenorrhœa. That the blood when discharged is true menstrual fluid was not affirmed. Dr. Heywood Smith denied that it is, and Dr. Barnes, in reply, admitted that it is not. For our part, we do not profess to know what true menstrual fluid is, or, indeed, whether there is a true menstrual fluid at all.

Perhaps the subject is not of great clinical importance, but it is of interest from a speculative point of view. Practically we are inclined to agree with Dr. Heywood Smith, when he says he does not believe in the life and

death necessity for the performance of the function of menstruation.—*Med. Press*, May 12, 1886.

#### PITYRIASIS AND PHTHISIS.

Every physician is familiar with the cutaneous eruption occurring frequently on the chest and back of phthysical patients, which passes under the name of pityriasis versicolor, or chloasma, and the fact that it is due to the presence of a fungus allied to those which cause favus and ringworm is well known; but no one has at present suspected that its presence had any significance, or that it had any real connection with the essential lesion of phthisis. It was regarded as a fungus which took advantage, so to speak, of the exhausted and debilitated condition of the patient to take up its abode in his skin, and it occurs in other wasting diseases of a similar nature. That it is contagious and can grow on the healthy skin is shown by the story which is told of the French pathologist Lancereaux, who, wishing for a drawing of the fungus for his plates on pathological anatomy, took some skin scrapings in an envelope in his pocket, and was surprised after a time to find a plentiful crop of the parasite not only on his own chest but on that of his wife. But the fungus has now come before us in a new light as playing a prominent part in the production of tubercular phthisis. According to the researches of MM. Duguet and Héricourt, the results of which were given to the Academy of Sciences on April 19, certain cases of acute tuberculosis presented no bacilli or zoogloea forms; but when the tissues were treated with potassium (ten to forty per cent.), a delicate mycelium allied to that of microsporon was discovered; and on pushing the inquiry further it was found that this mycelium was more frequently present than the bacilli, being seen not only in the tubercles but also in the neighboring healthy tissue. Similar mycelial threads can also be found in the expectoration mixed with the bacilli. When the microsporon furfur is cultivated and injected into guinea-pigs and rabbits, these animals become, without exception, tuberculous, and the same result is obtained by insufflation into the trachea of the crusts of pityriasis. Moreover, the cultures of microsporon furfur, of tubercle produced from the fungus, and those from tubercles of man are precisely the same in character. Cultivations can be made in slightly alkalized bouillon or in milk, when it becomes possible to distinguish an aerobic

and an anaerobic element. The former floats at the surface, and at a temperature of from 30° to 38° C. forms a thick membrane composed of bacilli. The latter is found at the bottom of the cultivation-tube as a mass of granulations and mycelium. The polymorphic character of the tubercle bacillus is thus manifest, and the opinion of Spina receives support as to the variety of the forms of microbes in tuberculosis. The whole question is an interesting one, and it cannot be said to be yet settled whether the various forms of low vegetable life to which we assign names are not phases in the life history of one species modified by chemical and physical conditions. The authors regard their discovery as important from the possibility of obtaining an attenuated virus.—*Lancet*, May 8, 1886.

#### ADONIDIN.

This glucoside is prepared by macerating the plant *Adonis vernalis* for ten days in hydrated alcohol (alcohol 1 part, water 2 parts). The resulting tincture is precipitated by lead subacetate. It is then filtered and condensed and treated with tannin and a few drops of ammonia, which produces adonidin tannate, which is then washed with water and decomposed with zinc oxide and alcohol. Adonidin results in an impure state, and is purified by successive crystallizations in alcoholized ether. It is a bitter-tasting, amorphous, clear yellow powder, insoluble in ether or chloroform, slightly soluble in water, most soluble in alcohol. Muriatic acid colors it gray, nitric acid yellow, sulphuric acid red. Every part of the plant contains it. Ten kilogrammes of the plant yield two grammes of adonidin. It has all the advantages of digitalis, without its cumulative action.—*National Druggist*, May 7, 1886.

#### A CLEANLY AND ECONOMICAL METHOD OF APPLYING OINTMENTS.

At a recent meeting of the Manchester Medical Society, Dr. BROOKE (*Brit. Med. Journ.*, May 20, 1886) exhibited a number of ointments, prepared with a solid base, composed of cacao butter, wax, and oil, or lanolin, and cast into the form of sticks ("salvesticks"). He had found them particularly useful in making applications to the face and hands, since, their melting-point being high, they did not run at the temperature of the body, as did ointments prepared with the or-

dinary bases; and, when dusted over with powder, they were practically invisible. When covered with Mather's, or Seabury and Johnson's adhesive rubber (waterproof) plaster, they offered a mode of applying remedies to the skin which was more durable than the Unna-Beiersdorf plasters, and less expensive. With this protective covering, they were especially applicable to the treatment of psoriasis by chrysarobin, and possessed several advantages over the methods of Pick, Auspitz, and Besnier, in that the fatty menstruum was preserved; they did not need such frequent renewal; they were more readily applied, and did not cause any disagreeable dragging on the skin and hairs. The fear of staining the clothing was completely removed, and the patient might, moreover, bathe without disturbing the dressing. They were supplied enclosed in small cases, like those used for cosmetics, so that they could be conveniently carried in the pocket.

#### PHOTOGRAPHING THE UTERINE CAVITY.

According to the *Lancet* for May 15, 1886, a Swiss physician describes a plan of introducing wadding tampons and laminaria tents into the uterus, by which he has succeeded in dilating the organ to such an extent as to be able, by means of reflectors, to get a complete view of the whole cavity in cases of carcinoma, fibrous polypi, fibromata, and endometritis. Not being content with ocular inspection, he has also contrived to obtain photographs of the cavity. New inventions for uterine exploration, medication, and instrumentation are often of a somewhat hazardous nature, but we tremble to think of the future of some female patients if photographing the interior of the uterus should ever become one of the medical fashions of the day.

HON. DAVID A. WELLS's third paper of the series, entitled "An Economic Study of Mexico," now running through *The Popular Science Monthly*, will appear in the forthcoming June number. The series will close with the fourth paper, and it promises, when completed, to be the fullest, as it will unquestionably be the most accurate summary of the real condition of affairs, industrial, commercial, and political, in Mexico, that has appeared since the Mexican war.

### THE PATHOLOGY AND TREATMENT OF DROPSY.

BY JAMES BARR, M.D.\*

*Read at the Liverpool Medical Institution, April 15, 1886.*

**D**ROPSY in its widest sense may be defined as an abnormal accumulation of serous fluid in the cellular tissue or in a serous cavity. It may be either general or local, and, according to the position which it occupies, has received various designations, such as anasarca, œdema, hydrocephalus, pleural effusion

and hydrothorax, hydropericardium and pericardial effusion, ascites, hydrocele, hydrops articuli, acute local œdema, hydrops oculi, ovarian dropsy, hydrosalpinx, etc.

In the ordinary process of nutrition there is a more or less constant transudation of serum from the capillaries, which bathes the tissues in this nutritive pabulum, of which they make use according to their selective affinities, and then it is reabsorbed along with the waste products by the veins and lymphatics.

It is usually asserted that when the balance between transudation and absorption is disturbed dropsy results, so that this condition may be due to excessive transudation or defective absorption. However true these state-

\* Physician to the Stanley Hospital, Liverpool; Medical Officer to H.M. Prison, Kirkdale.

ments, the consideration of the conditions under which they arise is much more complex than their broad assertion would seem to indicate. About two-thirds of the weight of the whole body is composed of water, and in the soft tissues of course the percentage is much higher. In health the proportion in different individuals varies, and in disease there may be considerable effusion into the soft tissues before there is any pitting on pressure which would make the condition merit the name of dropsy. In many cases, where I have seen the dry parchment-like skin and contracted features of old age give place to a smooth skin and full rounded features, I have been prepared for the advent of dropsy when the friends and patient were looking upon the appearance as evidence of gaining flesh and returning health. In health the blood-vessels are never fully distended, and the quantity of fluid which they contain is constantly varying. The veins themselves are capable of holding all or more than all the blood in the body. A considerable over-repletion of the blood-vessels may occur without any abnormal transudation, so long as they retain their vaso-motor tone and the velocity of the blood is not materially diminished. In health the quantity of urine secreted often varies very considerably from day to day independently of the quantity of fluid taken in or the amount lost by other sources, and this is due to the varying capacities of the blood-vessels. You all know the diuretic effects, independently of drinking, of hard mental work, and the profuse diuresis which follows an hysterical attack owing to the increased vaso-motor tone.

Not only does this tone and elasticity of the blood-vessels regulate the amount of fluid which they contain, but the elasticity of the tissues is also concerned in regulating or limiting the amount of fluid which transudes into their intercellular spaces. The loss of this elasticity in disease is a potent factor in the production of dropsy, and also an obstacle to our efforts to remove the disease.

Dropsies may be divided into two classes: (1) Those cases in which there is an abnormal transudation from the capillaries without apparent obstruction in the absorbents, such as occurs in inflammations, in vaso-motor paralysis, in anæmia, in Bright's disease, etc. (2) Those cases in which there is obstruction to the return current, whether local or general, such as the occlusion of a vein or lymphatic, portal obstruction from cirrhosis of the liver, or general venous obstruction from mitral or tricuspid regurgitation or obstructive lung-

diseases. The conditions which give rise to these broad distinctions are variously compounded in different cases, and the distinctions are here made more for facilitating clearness of description than for indicating any sharp lines drawn in nature.

When we come to consider the causes of abnormal transudation there are three conditions which must engage our attention,—(a) the condition of the walls of the vessels,—increased permeability; (b) the condition of the blood and its greater liability to transude; and (c) the pressure within the capillaries. This last condition we will consider first, as perhaps the most important, and a clear comprehension of it will help us to a better estimate of the value of the others. As the transudation takes place from the capillaries it is the condition of the blood within them with which we are here concerned, but in order to understand this we must take a brief glance at the general physics of the circulation. In a paper which I published in the *Liverpool Medico-Chirurgical Journal*, July, 1883, on the "Pathology and Treatment of Tubal Nephritis," I drew attention to the statical and dynamical conditions of the blood in the production of albuminuria, and extended those views to the production of dropsy. I wish now to follow out this paper much in the same lines there laid down.

There have been numerous calculations of the force of the human heart, but all the estimates can only be looked upon as more or less close approximations to the truth. You cannot attach a manometer to any of the large arteries in the same way you can experiment on the lower animals. Perhaps about the most accurate calculations have been made by Professor Haughton, of Dublin.\* In the course of an operation a large artery spurted very freely over the operating theatre in different directions. Dr. Haughton measured the co-ordinates of the maximum range, and thus calculated the velocity with which the blood left the artery. From this and the co-efficient of capillary resistance he calculated the force of contraction of the left ventricle. He estimated the force to be equal to four and a half pounds to the square inch, or a force equal to support a column of blood 9.923 feet high. It is quite beyond the province of this paper to enter into the physiological question of the correct force of the heart, as our object is only to deal with comparative forces arising under different conditions,

\* Principles of Animal Mechanics, 1873.

though it may be taken, I think, as a matter of fact, that the force of a healthy adult heart with normal arterial tension is capable of supporting a column of blood of eight to ten feet high. There can be no doubt that this force varies very materially in different individuals. In the same individual in a state of health the range of variation is perhaps slight, but in disease it may be very considerable. The *vis viva*, or energy imparted by the heart, may be represented by the formula  $\frac{MV^2}{2} = \frac{1}{2} \frac{W}{G} 2Gh = Wh = GMh$ .

Here  $h$  represents the height of the column of blood maintained by the force of the cardiac contraction, and it might be supposed that this column would be maintained at the same level, as in the case of a steam-pump set to do a certain amount of work,—irrespective of the resistance. But such is not the case with the heart. I have shown in several of my writings that the force of the contraction greatly depends on the amount of resistance, and when this is greatly lessened the force of the contraction is correspondingly diminished. In cases of copious loss of blood the column  $h$  falls rapidly, and the diminution in force may sink below that necessary to carry on the circulation, and so you may have fatal syncope. This no doubt is due to the low tension in the aorta being insufficient to drive the blood through the coronary arteries, and thus the heart is not supplied with a sufficient amount of fuel to enable it to maintain the force of its contraction. This would correspond to the fire going out in the case of the steam-pump. This is a most important point to bear in mind in the treatment of dropsy by purgation, or by rapid removal of fluid by mechanical means; as you may thus, in many cases, so rapidly deplete the arterial system as to arrest the action of a feeble heart. I will have to refer to this part again when I come to speak of treatment.

Thus, low arterial tension lessens the force of the cardiac beat, while high tension raises it so long as the heart is capable of meeting the resistance. This, however, may be so great as to overpower the heart, and tell backwards through the lungs on the general venous system, thus tending to equalize the pressure, and so the arterial column  $h$  in this case also falls.

The velocity in the arterial tree depends on the force of the cardiac beat, or, in other words, on the height of the column  $h$  (velocity,  $V = \sqrt{2Gh}$ ). If the arteries were rigid tubes, with a given force, the velocity would be simply inversely as the sectional areas of the ar-

teries at different distances from the heart, and the current would intermit with the beats of the heart. In cases of high tension, a considerable amount of the energy is stored up in the elastic walls of the arteries, and this tends to make the velocity more or less uniform. In cases of very low tension the arteries are not much distended, so that they in great part act as rigid tubes, and thus the velocity becomes more or less intermittent.

We have previously seen that in low tension the column  $h$  (on the square root of which the velocity depends) falls so that the mean velocity is diminished. Now, this great or total velocity, in cases of high tension, is maintained in the arterioles and capillaries so long as there is no obstruction to the outflow from them into the veins. It is still further augmented in these minute vessels over that existing in cases of tension, for the following reasons: The high arterial tension is mainly induced by the obstruction to the arterial flow through the contraction of the lumen of these vessels, and as the velocity is inversely as the sectional areas, so, with equal forces, the velocity in contracted capillaries is greater than in those which are dilated. If the blood were a perfectly mobile liquid, and free to move without any resistance, the force of the cardiac contraction would be converted into velocity, and there would be very little lateral pressure on the walls of the vessels. But the blood is a very viscous fluid, and there is also considerable resistance to its flow from the capillaries and arterioles, and from the friction against the walls of the vessels; thus the velocity is diminished and the statical condition partly maintained. Part of the work of the heart is thus converted into stored energy in the elastic walls of the arteries. This distention of the elastic walls gives rise to what engineers call a head in the liquid, and this, in turn, imparts further movement to the blood during the interval between the beats, equalizes, and makes the discharge continuous. It is well known that in propelling fluid through rigid tubes a considerable amount of the force is used up in friction of the molecules against each other and against the sides of the tubes, so that in about two hundred feet the discharge is reduced to one-fourth.

In elastic tubes this waste of force is very much reduced, and so the discharge is much greater, and when the tube is very elastic there is not much waste from friction. All these physical conditions come frequently into play in the human circulation. When the aorta and large arteries are healthy, and

there is moderate tension, the force of the heart is used in propelling the blood onwards and storing its work in the elastic coats of the vessels, which is again expended in the onward movement of the blood between the beats. When the aorta is very atheromatous it plays the part of a rigid tube, and when the tension is very low the elasticity of the vessel is not made use of, so that the heart is in part wasting its energy in pumping blood into empty tubes. In the former case the heart meets the increased resistance so long as it is capable of hypertrophy, but in the latter case, there being diminished resistance, and no demand for increased force, there is no hypertrophy, and the heart wastes its energy in futile efforts to carry on the circulation, as happens in many febrile affections.

In very low tension, if the heart be at all vigorous, the velocity is increased during the period of systole, and the intermittent pulsations may be carried right through the capillaries into the veins. In proportion as the velocity is increased the lateral pressure is diminished, and so there is lessened interchange between the blood and the tissues. This readily accounts for the rarity of general anasarca in most febrile affections, for, although in many instances the force of the heart is greatly lessened, the resistance is correspondingly diminished, and there is no great lateral pressure in the capillaries; the *vis viva* is converted into velocity, and the statical condition of the blood is lessened.

On the other hand, in many cases of low tension, such as cases of mitral regurgitation, part of the force of the heart is expended in the wrong direction, the veins and capillaries are overfilled with fluid, there is, consequently, an obstruction to the onward movement of the blood, the velocity is diminished, and the statical condition increased, and so we get dropsy.

It seems to me that there is often a great confusion between high arterial tension and the amount of lateral pressure on the walls of the capillaries. It is generally supposed that both stand in a direct ratio to one another, but I hope to show that this is a *non sequitur*. This is a most important point to understand, because in dropsy the effusion takes place from the capillaries, and therefore it is with the condition of the current in them we are immediately concerned in the production of dropsy. High arterial tension may be produced in one or both of two ways: (*a*) by increased inflow from the heart, or (*b*) increased resistance to its exit through the arterioles and capillaries.

No matter how high the arterial pressure, it does not imply increased lateral pressure on the walls of the capillaries so long as there is no obstruction to the flow from them into the veins. The force of the heart is a very varying quantity, and, as I have shown in my papers on reduplication of the heart's sounds,\* is directly proportionate to the amount of resistance, so long as this does not exceed the capabilities of the heart. This increased obstruction to the outflow from the arteries calls forth greater force from the heart, the aorta is stretched, the head of the liquid is raised, and so long as the heart maintains this force, and there is no obstruction to the flow from the capillaries to the veins, the velocity in the former is increased. Once, however, the heart is overworked and begins to fail, the blood increases in the venous radicles, and there is increased obstruction to its exit from the capillaries, the velocity is diminished, and the statical condition increased. This is the condition which occurs in the general anasarca of acute Bright's disease, and here the statical condition is further augmented by the retention of fluid within the system, which overfills and distends all the blood-vessels. This may also be expressed by the law that the velocity is inversely as the sectional area. The effect of increased sectional area in diminishing the velocity and augmenting the statical condition is well shown in local œdemas due to vaso-motor paralysis. Here the blood-vessels are dilated, and contain an excessive amount of fluid, which moves slowly, exercises considerable lateral pressure, and so readily transudes into the yielding tissues. It is from the capillaries that transudation takes place, and these conditions clearly explain the absence of dropsy in the early stages of granular kidney, where you have great cardiac force and rapid velocity. We have previously

seen that the *vis viva* equals  $\frac{MV^2}{2}$ , and  $V^2 = 2Gh$ , so that, when the mass remains constant, any increase in the *vis viva* is converted into velocity, and the statical condition or pressure is relatively diminished. Further, the statical condition depends on sectional areas, because the larger the area the greater the mass and the less the velocity. Hence, under any circumstances the total lateral pressure within the capillaries is greater than that in the arteries or veins, and of course the greater the section of the capillary area the

\* *Medical Times and Gazette*, 1877; *Liverpool Medical-Chirurgical Journal*, July, 1882.

greater the lateral pressure within them, but the less the resistance offered to the heart. Professor Haughton has shown that capillary resistance is directly proportional to the length of the tubes, and inversely proportional to the squares of their cross-sections. Resistance tells backwards in the course of the circulation. Obstruction to the flow of blood into the arterioles and capillaries raises the arterial tension, and venous engorgement raises the pressure within the capillaries. High arterial tension may lead to engorgement of the lungs, and pulmonic obstruction to overloading of the systemic capillaries and veins. The blood tends to move in the direction of least resistance, and hence the amount of transudation through the walls of the capillaries will be directly as the statical condition or pressure within them and inversely as the velocity. This leads us up to the question of the relation of the amount of fluid within the vessels to dropsy. Owing to the action of the vaso-motor nerves the arteries are capable of undergoing considerable alteration in capacity. When they are dilated a larger quantity of blood is supplied to the capillaries, the elastic walls of which dilate and allow of a corresponding increase. When there is no defective elimination of fluid from the body, and no obstruction to the flow from the capillaries, there may be no extra filtration through their walls. This increase of fluid in the body may be limited to over-repletion of the vascular system, which may just act as a temporary reservoir. When, again, the vaso-motor nerves contract the arteries and arterioles, the arterial tension is raised, the blood is driven with increased velocity through the capillaries, and consequently the lateral pressure within them is diminished, and so the elastic walls contract and reduce their dimensions. Thus the temporary reservoir is abolished, and its contents may be discharged by an abundant secretion of urine. If there be any defective elimination, the fluid soon accumulates, and from its mere bulk becomes an obstacle to the propulsive power of the heart, the velocity is diminished, and the statical condition increased, and the filtration through the capillary walls is augmented. There is also increased pressure and over-repletion in the venous radicles, and consequently diminished absorption.

Fluids pass very readily through organic membranes, such as compose the walls of the capillaries, by a process of osmosis, but albumen does not thus readily transude. Unlike the capillaries of the lungs and kidneys, the

systemic capillaries allow albumen to pass easily through their walls, so that it is found in all the intercellular fluids. Now, if it does not pass through by osmosis, we must suppose it to be filtered through under varying amounts of pressure. In filtering under pressure, as a rule, the greater the pressure the greater the amount of the filtrate, but the composition of the latter differs very materially from the nature of the compound fluid submitted to pressure, as the different constituents pass through with varying degrees of ease, the water passing much more readily through than the albumen. Hence, although the total amount of albumen passed through may be increased according to the quantity of the filtrate, its percentage is diminished. Hence the greater and more rapid the production of dropsy—if there be no increase in absorption—the less the relative amount of albumen.

*The Condition of the Walls of the Capillaries.*—We have seen the varying effects of pressure within the capillaries, and we now come to consider the condition of their walls. The capillaries of the lungs and kidneys are well protected by an epithelial covering, and do not readily allow the passage through them of albumen, but in certain diseased conditions their secretions may be highly albuminous. The systemic capillaries allow of a filtrate of albuminous and watery constituents of the blood, and no doubt this takes place more readily when the elasticity of the vessels is lessened. We have seen how vaso-motor paralysis increases the sectional area of the capillaries, diminishes the velocity, and increases the statical condition of the blood. This augments the difference between its pressure within and outside the capillaries, increased transudation takes place through the more permeable walls, and this goes on until an equilibrium of pressure within and without the capillaries is established. The diminished resiliency of the tissues does not tend to drive the fluid into the veins, in which there is, in this case, more than ordinary pressure.

Under this head may be included the numerous cases which occur in the practice of surgeons from, shall I say, their too judicious treatment of fractures. In many cases of paraplegia you may have no dropsy, while in others there may be extensive brawny oedema and the formation of bed-sores, owing to the involvement of the vaso-motor nerves.

In inflammation there is vascular dilatation and increased permeability of the walls, which give rise to oedema or effusion of fluid into a serous cavity.

*The Condition of the Blood itself.*—The more watery the fluid the more readily does it pass through the walls of the vessels both by the processes of osmosis and filtration. Some have supposed the more watery the fluid the greater the resistance to its flow along the vessels, but such is not the case. In fact, by diminishing the viscosity, the very reverse should happen. When the blood is very hydræmic, however, the heart is not so well nourished, its force is not so well maintained, and at the same time it is handicapped by the increased quantity of fluid to move along. Hence the blood, although from its quality it may offer less resistance, has less energy, moves with a less velocity, its statical condition is increased, and it filters more readily through the walls of the capillaries. These are the conditions existing in the dropsy of anæmia. Although you have generally got high arterial tension, the vessels are dilated and the force of the heart is very materially lessened, so in the *vis viva* the mass is increased but the velocity is decreased. The blood flows slowly through the capillaries; its lateral pressure within them is increased, and transudation of the watery fluid readily takes place, especially in the feet and ankles, where there is superadded to this general condition the obstruction to the flow from the capillaries into the veins, owing to the action of gravity and the weight of the venous column of fluid.

Dr. Lauder Brunton, in the article on "Dropsy" in Quain's "Dictionary of Medicine," states: "In albuminuria the altered composition of the blood appears to be the chief factor in the production of œdema, as the pulse in such cases may be hard, evidencing arterial contraction and not relaxation." This, in my opinion, is an over-statement of the influence of the condition of the blood. The high tension may overpower the left ventricle, there may be a damming back of the blood in the lungs, and systemic veins obstructing the flow from the capillaries. However, there is diminished excretion of fluid, the blood-vascular system is overfilled, and so within the capillaries there is increased pressure and diminished velocity. There are more ways of accounting for it than merely the watery condition of the blood. However, we will have more to say of this again.

We now come to consider the second main class of dropsies, viz., those due to defective absorption, whether local or general, such as arise from the occlusion of a vein or lymphatic,

or general venous obstruction from mitral or tricuspid regurgitation or obstructive lung-diseases. This forms a large and important class; usually in these cases there is not merely defective absorption, but the obstruction may also give rise to overpressure within the capillaries with increased transudation.

The veins are the chief absorbents, and venous obstruction is a more common source of dropsy than occlusion of the lymphatics.

Although a vein be obstructed, it is possible, if the transudation be very slight, that the lymphatics may absorb the fluid, and so there be no dropsy. On this point, Dr. Lauder Brunton, in his article on "Dropsy" in Quain's "Dictionary of Medicine," quotes the experiments of Ranvier, who found "that ligature of the vena cava in a dog does not usually produce œdema of the lower extremities, but if one sciatic nerve be divided in such an animal, the corresponding leg at once becomes œdematous. The reason of this is, that so long as the nerve is intact the lymphatics can absorb all the fluid which exudes from the capillaries, but when the nerve is divided the arteries dilate, more fluid is passed out than the lymphatics can absorb, it accumulates in the tissues, and œdema ensues. This œdema is not due to paralysis of the limb, but to paralysis of the vessel; for, if the sympathetic fibres through which the vaso-motor nerves pass to the sciatic nerve are divided before they join the motor fibres of that nerve in the sacral plexus, the power of movement remains unimpaired, but œdema occurs just as if the whole nerve had been divided. If, on the other hand, the motor strands of the sacral plexus are cut before they are joined by the sympathetic fibres, the limb is as completely paralyzed as if the sciatic nerve had been cut, but no œdema takes place."

In the case of the dog, there is not much loose cellular tissue in the hind legs, the vessels are well supported by the good tonicity of the tissues, the blood-supply is not great, and, so long as the vaso-motor tone is maintained, even with the vein occluded, the pressure within the capillaries cannot rise very high, perhaps very little higher than that on their external walls. Tying the vein brings the blood in the extremity to a standstill, the vaso-motor nerves contract the arteries, and very little blood enters the limb; the force of the heart or weight of the blood-column acts on a comparatively small mass of blood, and therefore the hydraulic pressure is not greatly raised.

Once, however, the vaso-motor nerves are cut, the vessels are paralyzed and dilated, and the quantity of blood greatly augmented, with a corresponding increase in the hydraulic pressure. When the return of blood from a limb is wholly prevented, the onward movement of the blood is stopped, and the pressure within the tubes becomes a question of hydraulics.

Fluid pressure depends on the depth of the liquid, and, as the statical pressure is equal in all directions, its total sum will depend on the area. When a vein is occluded in a dependent limb, you have the weight of the arterial and venous columns of blood tending to dilate the capillaries, and, as the pressure at any given depth is equal in all directions, the total pressure within the capillaries will be proportionately greater than that within the arteries and veins as their sectional area is greater.

To the statical condition of the blood within the limb you have superadded the force of the heart or the pressure of the arterial blood-column. This may be expressed in so many pounds to the square inch, and so the greater the amount of fluid on which it acts the greater the total pressure. We must see why, in these cases, when the vaso-motor nerves are divided, the pressure is so much greater. These arguments, of course, apply not merely to a limb, but also to any area from which the blood is wholly prevented from returning by the occlusion of the veins.

When the return current is not wholly prevented, such as in portal obstruction from cirrhosis of the liver, the effects are correspondingly less. This also applies to the amount of obstruction to the general circulation from tricuspid regurgitation. I know a case at present where I believe there is total occlusion of the lower part of the vena cava, but the collateral circulation is so well established through enormously dilated superficial veins of the abdomen that there is no dropsy.

Cases of dropsy, arising from obstruction of the lymphatics, are not very common. In cases of lymphangitis, there is considerable brawny swelling, though this is no doubt due to involvement of the capillary blood-vessels. I have seen considerable œdema of a lower extremity arise from inflammation of the lymphatics around the femoral artery. Dr. Whittla lately recorded a very interesting case of chylous ascites arising from perforation of the thoracic duct.\*

Various forces combine to carry on the circulation in the lymphatic vessels; the current is very slow, and even in the thoracic duct it is reckoned not to exceed one inch per second. Among the chief of these forces must be mentioned osmosis. The great attraction which albumen has for water must cause an endosmotic current into these vessels, but in cases of œdema, where the effused fluid is highly albuminous, the force of this current must be diminished. The pressure of the muscles and the elasticity of the tissues also largely contribute to the onward movement, and the innumerable valves with which the lymphatics are supplied secures the full benefit arising from these forces. When the elasticity of the tissues is lost, and the activity of the muscles diminished, as in dropsy, there will be a corresponding diminution in the velocity of the lymph current. The thoracic duct discharges its contents into the junction of the left internal jugular and subclavian veins, where the pressure is usually negative, and so each inspiration must contribute to the onward movement of the lymph. Dr. Lauder Brunton thinks that in the pleura and peritoneum, which are now generally looked upon as large lymph-sacs, the respiratory movements play an important part in the absorption of and carrying on the circulation of the lymph. From a full consideration of all these conditions we cannot attribute more to the lymphatics and the condition of the tissues than a passive action in the production of dropsy.

Having now fully dealt with the general question of dropsy, we will consider the etiological factors in the causation of its different varieties. General anasarca, of which we will first treat, is usually supposed to be due to hydræmia, though opinions differ as to how the watery condition of the blood is brought about. Some observers, who are endowed with a very small horizon, can trace all the evil effects of Bright's disease to the loss of the albumen, and imagine that the low specific gravity of the blood-serum is due to the loss of this solid constituent. They fail to see that the blood can be more readily diluted by the addition of water than by the abstraction of its solids.

Bartels, Grainger Stewart, Carter, and a host of others recognize the fact that dropsy frequently occurs when there has been little or no loss of albumen, and they correctly ascribe the hydræmia to retention of water in the system. Dr. Carter† deals fully with the

\* *British Medical Journal*, May 30, 1885.

† *Renal and Urinary Diseases*, 1878.

effects of velocity and pressure in the circulation, and shows how the water is not eliminated by the kidneys, but he leaves the question there, and does not show how the transudation takes place into the cellular tissue. The defective elimination of fluid necessarily increases the amount retained in the system, and we have now to consider the mechanism by which it is transuded into the tissues. If you have got several water-taps in connection with the same main pipe in your house, and you turn them all on, the first one or two taps may be able to empty the pipe, and there may be no efflux from the more distant ones. Now, if you shut the proximal taps, the flow takes place from the more distal ones. The flow, in this case, is not immediately due to the closure of the other taps but to the pressure of the liquid. So with the closure of the kidney taps.

In my paper on the "Pathology and Treatment of Tubal Nephritis" I stated,\* "In acute Bright's disease the heart's action is vigorous, and at first it is quite able to meet all the demands which are made upon it; the surplus of expulsive power is great, overtops the high arterial tension; the blood is driven with considerable velocity through the contracted and even the most remote arterioles. The function of the kidneys, however, is suppressed; the excess of water is not got rid of by the skin and lungs, hence it accumulates in the blood-vessels, and gives rise to increased statical pressure within them. The pressure soon more than counterbalances the velocity of the blood, and so abnormal transudation takes place into the cellular interstices of the tissues, and probably also, in many cases, into the serous cavities. The pressure, however, is universal, and not simply a pressure occurring in greater degree at the most extreme points of the circulation, as in adynamia, hence the effusion first takes place from the capillaries which are least supported; thus the dropsy usually first appears in the loose cellular tissue of the lower eyelids, from whence it quickly spreads over the whole body. In some cases you may see œdema of the lower extremities during the day, which partly subsides at night, giving place to swelling of the lower eyelids in the morning. If the heart's action fail, you get pulmonary congestion and œdema, which still further obstruct the venous return and increase its results."

Anasarca due to kidney-disease is usually associated with acute Bright's disease, the

large white or fatty kidney, to a less extent in amyloid disease, and it may occur in the last stage of granular kidney when the heart begins to fail. Dropsy occurs most readily in those cases where there is a large retention of fluid, which increases the statical condition of the blood, gives more work to the heart, diminishes the velocity, and causes the blood-serum to transude more readily into the tissues. In the early stage of granular kidney the blood-vessels are contracted, with a corresponding diminution in the mass of blood in circulation, the arterial tension is high, the heart's action vigorous, which imparts great velocity to the blood and carries it not only quickly through the systemic capillaries but also through the kidney, where the surplus fluid is eliminated. Dropsy due to disease of the kidneys commences in the cellular tissue, then extends to the serous cavities, where the vessels are better supported and transudation less likely to occur, and lastly produces œdema of the lungs.

Senator, in his classical work on "Albuminuria in Health and Disease," makes, to my mind, the following extraordinary statement:† "In addition to the fact that dropsy is as constant in the one type (large white kidney) as it is rare in the other (granular kidney), the way in which this symptom makes its appearance is so peculiar that the idea suggests itself that some disease of the skin is concerned in its production.

"It is perfectly evident that the dropsical effusion cannot be referred to suppression or diminution of the urinary secretion, an explanation advanced by some observers. Even the complete interruption of the discharge of urine, which may originate from obstruction in the urinary passages, does not, *per se*, produce dropsy as a consequence. Cohnheim very particularly refers to the fact that neither hydræmia nor hydræmic plethora can be the cause of dropsy in those diseases of the kidney.

"Its proportionately rapid supervention, the great extent of the anasarca, and above all its localization, would rather seem to indicate the existence of special local abnormalities, which Cohnheim is inclined to look for in some inflammatory change of the skin or its vessels. It is in fact difficult, without some such assumption, to explain how it comes to pass that, in the first form of chronic nephritis (and also in acute nephritis), the eyelids or the scrotum are the usual seats of the œdema, and often those which are first affected; for, as

\* *Liverpool Medico-Chirurgical Journal*, July, 1883.

† New Sydenham Society's Translation, 1884.

regards these parts, the influence of gravity cannot be a sufficient cause for the appearance of the symptom."

The refutation of these statements ought to be sufficiently clear from what I have previously stated, but I may also add that complete suppression of urine does not necessarily produce dropsy, because there may be no greater quantity of fluid imbibed than is got rid of by other channels. I have seen general anasarca appear and disappear many times in the same case, where there was no alteration in the state of the skin, and the treatment on each occasion consisted mainly in the diminution of the amount of fluid ingested. There may be sufficient pressure within the capillaries to produce oedema without any influence from gravity. When the pressure outside the capillaries is much less than that inside, transudation is apt to take place. I have shown that there is this greatest difference where the capillaries are least supported in the loose cellular tissue of the eyelids, scrotum, etc.

In anæmia the dropsy usually commences in the feet and ankles, or other dependent parts. The conditions present are dilated vessels, high arterial tension, and feeble heart. The dilated vessels increase the mass of blood, and the statical pressure being as the depth of liquid the total pressure within the capillaries is great. To this must be superadded the force of the heart. The effect of position in these cases is very great, for the following reason: When the limb is dependent you have the force of gravity plus the force of the heart, whereas when the limb is raised you get the force of the heart minus the force of gravity. The velocity within the capillaries depends on the force of the heart or height of the arterial blood-column and the sectional area of the capillaries, and as the former is weak and the latter great the velocity is much reduced, and the pressure much increased. Moreover, the watery condition of the blood and diminished pressure outside the capillaries would allow the serum to transude more readily.

I have before sufficiently explained the mechanism of acute local oedemas due to vaso-motor paralysis. In the case of dropsy arising from inflammations, such as peritonitis, pleuritis, pericarditis, synovitis, meningitis, inflammation of the soft tissues, etc., the vessels are dilated and become more pervious, the quantity of blood is augmented, the statical pressure increased, and the velocity diminished. The fluid transudes under high pressure, and there is also a considerable amount of coagu-

lable lymph poured out as the result of the inflammation, which forms a coating over the serous surfaces, thus obstructing absorption by the veins and lymphatics.

Dr. Lauder Brunton\* says that "accumulation of fluid in the ventricles of the brain, or in a subarachnoid cavity, is chiefly due to compression of the veins of Galen." I think it will be generally found to arise from excessive transudation independently of any obstruction. In cases of chronic alcoholism and chronic Bright's disease there is usually more or less wasting of the cerebral cortex, which is replaced by an excessive amount of cerebro-spinal fluid. This may be readily increased at any time under high pressure, when there is a state of hydræmic plethora. The watery brain becomes compressed with resulting stupor and coma.

In ovarian cysts, hydrosalpinx, hydrocele, etc., the pressure within the capillaries is greater than that on their external walls, hence transudation takes place into the cyst. Immediately after tapping, the hydrostatic pressure within the cyst is slight and effusion takes place rapidly, but as a cyst gets full the greater pressure supports the capillaries and transudation takes place more slowly. Dr. W. H. Stone† found the cyst tension in cases of ovarian dropsy to support a column of water fourteen inches in height, and in one case, where the circumference of the cyst was forty inches, he estimated that this tension force would equal two hundred and sixty-five pounds. In the case of ovarian cysts mere transudation from the capillaries would scarcely account for the thick and highly albuminous character of the fluid, so it is probable that the cyst plays the part of an endosmometer. Fluid is secreted or poured out from the capillaries, and the more liquid portion is re-absorbed, so that eventually a concentrated albuminous fluid is left. The action of an endosmometer would also more readily explain the high tension, which is at least double that of ascites, and which must be the potent factor in the rapid enlargement or growth of the cyst. In many cases of pleural effusion the tension is negative, and contrasts markedly with the condition which we have just described.

*Obstructive Dropsy.*—Dropsy arising in cases of mitral regurgitation generally begins at the farthest extremity of the circulation, such as the feet, where the velocity is least and hydro-

\* Quain's Dictionary of Medicine, art. "Dropsy."

† *Medical Examiner*, Feb. 15, 1877.

statical pressure greatest. In these cases part of the force of the heart is expended in the wrong direction, and there is a corresponding diminution in the onward movement of the blood. There is a general accumulation of fluid in the veins, and obstruction to its flow from the capillaries. In the lower extremities there is also superadded the influence of gravity acting on the weight of the column of blood. In mitral stenosis and obstructive lung-disease the conditions are similar, except that there is no force transmitted backwards from the left ventricle through the mitral orifice.

In cases of tricuspid regurgitation the dropsy not unfrequently begins as an ascites. Here you have not merely, as in mitral disease, overloading of the venous system, which necessarily begins in the most distal veins, but there is a positive forcible backward impulse against the advancing current, which necessarily first tells on the large mass of blood in the vena cava and such main branches as the hepatic veins. The impulse may cause the whole liver to pulsate, and anyhow it obstructs the portal circulation, and may thus give rise to great effusion.

Cases of ascites resemble those of partial occlusion of a vein, and this part has been previously considered.

Hydrothorax and hydropericardium may be the result of excessive transudation from hydræmic plethora, such as that occurring in Bright's disease. They may also arise from venous obstruction owing to the pressure of an aneurism.

In hydrophthalmia there is great enlargement of the anterior half of the eye, with corresponding increase in the aqueous humor. Dropsy of the optic disk is probably as a rule due to venous obstruction, and the retinal artery being a terminal one the circulation in the affected tract cannot be relieved by collateral circulation. In detachment of the retina (sub-retinal dropsy) the serous effusion is most probably due to occlusion of some of the choroidal veins.

(To be concluded.)

#### JAMAICA DOGWOOD AS A HYPNOTIC.

BY F. SPENCER HALSEY, M.D., NEW YORK.

THE following is a report of cases in which the fluid extract of piscidia erythrina, or Jamaica dogwood, was used during my service at almshouse and workhouse hospitals during the summer of 1885 :

CASE I.—Bernard S. Large ulcer on foot. Great pain, and very restless at night ; opiates give no relief.

*April 20.*—Dogwood, 3i, at bedtime ; slept very well ; no untoward effects.

*April 21.*—Slept all through.

*April 22.*—Another good night.

*April 23.*—Dose lessened ; fair results.

*April 24.*—Repeated first dose ; good result.

CASE II.—Mary D. Phthisis. Unable to sleep on account of cough.

*April 28.*—Dogwood, 3i, at bedtime ; slept fairly well.

*April 29.*—Slept well all night.

*April 30.*—Did not sleep much.

*April 31.*—Repeated dose ; same effect.

CASE III.—Hannah J. Phthisis.

*May 4.*—Dogwood, 3i ; slept all night.

*May 5.*—Rested more quietly.

*May 6.*—Slept well.

CASE IV.—John R. Alcoholism. Very restless and wakeful.

*May 5.*—Dogwood, 3i ; slept all night, and awoke refreshed.

*May 6.*—Slept very well.

CASE V.—John A. Chronic Bright's disease. Has not slept well for five nights.

*May 12.*—Dogwood, 3i ; slept almost all night.

*May 13.*—Did not sleep as well.

*May 14.*—Repeated dose ; no better result.

CASE VI.—Maria F. Alcoholism. Gave dogwood, 3i, night of May 20. Patient slept all night.

*May 21, 22, 23.*—Repeated dose ; same effect each night ; good night's rest ; and awoke with no unpleasant feeling.

CASE VII.—Henry M. Phthisis. Unable to sleep on account of cough, which is very troublesome. Has tried potass. brom., tr. hyoscyam., and other hypnotics with no good result. On night of June 5 gave dogwood, 3i, with the result that patient slept fairly well ; less cough.

*June 6-10.*—Gave dogwood each night, during which patient slept well, and was less troubled on awakening than with any other medicine he had taken.

CASE VIII.—William S. Fracture of radius. Unable to sleep on account of pain in arm. Ordered dogwood, 3i, to be given him on night of June 30. Slept all night.

*July 1, 2, and 3.*—Gave same dose, on all of which nights the same effect was obtained.

CASE IX.—Maggie McD. Compound fracture of the olecranon. Cannot sleep on ac-

count of pain ; very restless. Opium or morphine makes her worse ; bromide has no effect unless given in very large doses. Tried dogwood, 3i, during night of August 2, and found it to work very satisfactorily, patient sleeping nicely all night.

August 3.—Same result.

August 4, 5, and 6.—Slept well all night.

August 10.—Again given ; good sleep.

August 12.—Same result.

CASE X.—Julia M. Syphilis. Considerable pain in both legs ; has not enjoyed a good night's sleep in a long time.

August 10.—Dogwood, 3i ; slept fairly well.

August 11.—3i ; slept all night.

August 12.—Did not sleep as well.

August 13.—Same ; did not sleep until after midnight.

August 14.—3i ; complained of severe pain in head ; no sleep.

August 15.—3ss ; no pain ; less restless.

August 17.—3i again ; slept well.

August 18, 19.—Same result.

August 20.—Repeated dose ; same effect.

CASE XI.—Martin W. Large varicose ulcer on leg. Suffers much pain ; opiates do not affect him pleasantly.

August 27.—He was given 3i of dogwood ; result, he slept very well.

August 28.—Slept all night.

August 30.—Same result.

August 31.—Repeated dose, with same effect.

CASE XII.—Lizzie K. Facial neuralgia. Suffers great pain in the side of her face, the pain increasing in severity. Ordered dogwood, 3ss, morning of August 31, and by afternoon she was much more comfortable ; repeated dose at night ; patient slept fairly well.

September 1, 2, and 3.—Gave 3i doses each night ; patient slept well all night.

CASE XIII.—Edward S. Suddenly taken night of September 5 with severe pains in the abdomen, vomiting, cramps, all pointing to an attack of cholera morbus. I gave him as soon as possible 3ss dogwood, and repeated dose in half an hour. Before the second dose had been taken the cramps had lessened, the pain greatly diminished, and, after the second, he fell into a quiet sleep, from which he awoke the next morning feeling much better.

On night of 7th he was given another dose of dogwood, 3i, and slept almost the entire night through, waking the next morning in a refreshed condition.

CASE XIV.—Henry J. Fell from his bed

night of September 20, and sustained a fracture of two ribs. He suffered considerable pain and uneasiness, and, not wishing to give him morphine, I gave him dogwood, 3i, and had the satisfaction of seeing him a couple of hours later in a deep sleep.

September 21, 22, 23, 24.—Was given dogwood, 3i, on each of these dates, and always with the same result, viz., a sound sleep, and with no unpleasant after-effects.

These few cases, culled from a number of months' experience in hospital practice, have led me to express my opinion as to the value of Jamaica dogwood. I have found it to be a most excellent hypnotic and anodyne ; in no one case of those in which I employed it has it failed to relieve pain and induce sleep. One great advantage connected with it is that patients, after taking it, awake with none of the unpleasant after-effects which opium induces. Not only does it relieve pain and produce sleep, but in many cases it relieves cough, notably the case in phthisis. This experience, though very limited, has induced me to become very much attached to this remedy, and in every case where such an action as comes from its use is indicated I have always employed it with most satisfactory results.

#### SACCHARIN.\*

BY L. WOLFF, M.D.†

UNDER this name a product of the coal-tar derivatives has been recently introduced for medical use. It was first produced by Dr. C. Fahlberg in 1879, who described it, together with Prof. Ira Remsen, in vol. i. page 426, of the *American Chemical Journal*.

To understand the chemistry of saccharin it is necessary to enter somewhat into the consideration of the aromatic group of hydrocarbons from which it is derived.

This series is known by the general formula of  $C_nH_{2n-6}$ ; i.e., every member of the group contains for the carbon atoms twice as many of hydrogen less six. The starting-point of this is benzene,  $C_6H_6$ , derived by distillation from coal-tar, and the second member toluene,  $C_7H_8$ , or methyl benzene, also written as  $C_6H_5.CH_3$ , another distillate from that source.

Toluene treated with sulphuric acid,  $H_2SO_4$ , so that the H adjoining the  $CH_3$  in the hydro-

\* Read at the Clinical Meeting of the Philadelphia County Medical Society, May 19, 1886.

† Demonstrator of Chemistry, Jefferson Medical College.

carbon chain will be substituted by  $\text{SO}_2\text{H}$ , yields orthotoluenesulphonic acid, expressed by the formula  $\text{C}_6\text{H}_4\text{CH}_3\text{SO}_2\text{H}$ .

This converted into orthotoluenesulphochloride,  $\text{C}_6\text{H}_4\text{CH}_3\text{SO}_2\text{Cl}$ , and treated with ammonia,  $\text{NH}_3$ , gives orthotoluenesulphamide,  $\text{C}_6\text{H}_4\text{CH}_3\text{SO}_2\text{NH}_2$ .

As toluene by oxidation is changed into benzoic acid, so is the toluenesulphamide changed when oxidized with potassic permanganate,  $\text{KMnO}_4$ , into benzoic sulphimide, or saccharin, and orthosulphobenzoate of potassium. This mixture, when treated with hydrochloric acid,  $\text{HCl}$ , leaves a precipitate of benzoic sulphimide,  $\text{C}_6\text{H}_5\text{CO.SO}_2\text{NH}$ .

This benzoic sulphimide, if treated with water, gives orthosulphaminbenzoic acid,  $\text{C}_6\text{H}_5\text{CO}_2\text{H.SO}_2\text{NH}_2$ , so that saccharin may be therefore properly termed an anhydro-orthosulphaminbenzoic acid.

Saccharin, prepared in this manner, is a white powder, composed of irregular crystals. It is very slightly soluble in water, not quite half per cent. dissolving at ordinary temperatures, while it dissolves readily in warm and boiling water, from which it crystallizes out on cooling. As forming sulphaminbenzoic acid when so dissolved, it has an acid reaction. It is readily soluble in alcohol and ether. Its salts, with the hydrates or carbonates of the alkaline metals, are readily soluble, but saccharin is separated out from such solutions on the addition of acids. Heated to  $220^\circ\text{C}$ . it melts, and is partially decomposed, and, when fused with potassic hydrate, it forms salicylic acid. Its most remarkable property, and that which makes it of advantage to medicine, consists in its intense sweet taste, which is so great that one grain if dissolved and neutralized in about ten pints of water (1 to 70,000), can still be tasted, while one grain of cane-sugar can only be detected at the utmost when dissolved in half an ounce of water, so that saccharin is about three hundred times sweeter than sugar, the taste of which it represents entirely in quality.

Professor Mosso has recently studied the physiological effect of saccharin, and published the results in the *Archivo per le Scienze Mediche*, vol. ix., 1886. According to his researches, it is not, like benzoic or salicylic acids, excreted in the urine as hippuric or salicyluric acid, but is found therein in the same chemical condition as ingested. Frogs can be kept indefinitely alive in a neutralized watery solution of saccharin. When injected under the skin, the urine tastes sweet within fifteen minutes, and continues so for several days. Experiments with dogs, when saccharin

is given in large doses, developed no impairment of nutrition, nor was during its use the amount of urea eliminated either increased or diminished. The urine of animals fed with saccharin is less prone to putrefaction. The amount of chlorides in the urine is increased during its use, while the phosphates and sulphates remain normal.

Animals on full diet, along with saccharin, increase in weight. On man, doses of 5 grammes (75 grs.) produce no abnormal effect, and the appetite is stated to be increased during its use. The uropoietic ways are the only eliminative tract for saccharin, which makes itself manifest in the urine half an hour after its ingestion. It may be summed up, therefore, that saccharin is not possessed of any toxic or deleterious effect on the human organism.

In therapeutics this new substance is destined principally as a corrective for the taste of other substances, and as a condiment for the use of persons suffering from diabetes mellitus, and those under treatment for the reduction of obesity.

In several experiments that I have made, I found it to correct the bitter taste of quinine materially if one part of it is added to two parts of the latter. As its solution forms an acid, which readily forms salts with bases, it can be utilized to combine directly with alkaloidal quinine to form a quinine sulphaminbenzoate.

In fermentative disturbances of the digestive tract, when sugar and carbohydrates are contraindicated, it may be used as a corrective for the nauseant taste of other remedies, especially so as it has decided antiseptic powers. It may also be used as a condiment for milk and other nutriments to be taken. To improve the taste of elixirs, wines, etc., it seems especially fitted, as they will under such conditions have the very desirable property of not deranging the stomach. The coffee and tea of diabetic patients may be sweetened with a grain or two of saccharin, and it may also be added with advantage to jellies and other foods for such patients.

That saccharin has a place in medicine and in the dietary list is undoubted, and that it is innocent in its effect commends it especially to a trial by physicians.

## ON THE DISCOVERY OF THE MYDRIATIC ACTION OF THE SOLANACEÆ.

BY DR. RUD. KOBERT.\*

THERE can be no doubt that the discovery of the mydriatic action of certain solanaceæ was a matter of great importance for therapeutic practice. Nevertheless, there exists a singular uncertainty, if not confusion, as to the time of this discovery and as to the discoverer himself. In fact, there is not a single book published in German, French, or English, in which I can find reliable data in regard to this matter.†

In order to mend this defect, I beg leave to gather for a historical discussion all pertinent material, which, as may be presumed, is no light task.

The Greeks and Romans understood by mydriasis a condition of visual weakness, together with a dilatation of the pupil. This definition can be found in Paulus Ægineta (iii. 22),‡ Celsus (vi. 6), and Isagoges; and is probably derived from the peculiar condition of visual weakness and pupillary dilatation invariably to be found in glaucoma. Some few authors, as Aëtius, designate improperly, also, other pathological conditions of the eye, such as phthisis bulbi, as mydriasis. In the presently accepted meaning—i.e., dilatation of the pupils§—the word appears to have been first used by Cælius Aurelianus (Chron. ii., p. 344).

The first mention of a mydriasis produced by preparations of solanaceæ|| we find in Galen's third volume of *Methodus Medendi*

(Edit. Kühn, tom. x., Lipsiæ, 1825, p. 171). This author states in the second chapter of the quoted volume that grave visual interferences and mydriasis may result by a too intensive local application of drugs containing mandragora or hyoscyamus. Dioscorides and Plinius Secundus do not appear to have known anything of this action, at least these writers never mention it, while mydriasis itself occurs in Pliny, who even mentions an artificial production of mydriasis by the seeds of anagallis. Galen, therefore, is unquestionably the first author who refers to the mydriatic action of two species of solanaceæ. Still, his in every way correct statement appears to have been wholly forgotten, for no subsequent writer ever speaks of this action, which fifteen hundred years later had to be discovered anew.¶

In 1686, Dr. Ray, a famous English physician, reported in his *Historia Plantarum* (vol. i. p. 680) that a lady coming under his observation had placed upon a small ulcer beneath the eye a belladonna-leaf, and had afterwards been annoyed by an excessive dilatation of the pupil. Simultaneously the lady lost entirely the power of the pupil to react on light. The physician regarded this defect at first as a matter of accident, until a repetition of the belladonna application taught him that a dilatation of the pupil and loss of reactive power for several days were the physiological effects of belladonna.

But this second discovery also was again forgotten, although Ray's work was largely read. Thus, Boerhave (1668-1738), however familiar with medical literature, says in his book *De Morbis Nervorum* (p. 371), expressively that the juice of belladonna had no influence upon the eye, while Van Swieten, in his commentary of Boerhave's *Aphorisms* (vol. iii. p. 363), quotes Ray's case. And quite independently of Ray's observation, Evers reported in the *Berliner Sammlung*, 1773, vol. v. p. 565,\*\* that he noticed in six persons *hebetudo oculorum* and *dilatatio pupillæ* as symptoms of the belladonna intoxication. Evers must accordingly be mentioned as the third discoverer of the mydriatic power of belladonna. Three years later the following case of poisoning occurred at

\* Professor of the History of Medicine and Pharmacology in Dorpat, Russia.

† The statements of A. Hirsch in the *History of Ophthalmology* (Graefe-Saemisch, Textbook of Ophthalmology, vol. vii. p. 235), appearing to be more trustworthy than those of other authors, have been adopted in the main in this paper.

‡ This interesting passage is rendered by Adams as follows: When the pupil does not appear changed in color, but much wider than natural, and when it sometimes wholly impairs the vision, and sometimes nearly so, and when every object appears smaller, the affection is called mydriasis. The cause of it is some redundant humor.

§ The word pupil, with its present signification, was used by Cicero (*De Natura Deorum*, ii. 57), who derives it from *pupula*, a little doll.

|| The identification of the solanaceæ of the ancients is a difficult and as yet but partially-solved problem, vide Sprengel (*Ped. Dioscorides de Mat. Med.*, Lipsiæ, 1829, pp. 602-605), Francis Adams (*Paulus Ægineta*, London, 1847, ii. pp. 218-19, and iii. p. 290), and Imbert Gourbeyre (*Recherches sur les Solanum des Anciens*, Paris, 1884). For our purposes it is of importance to know that all of the species in question have a mydriatic action.

¶ Ebn, Baithar, and Paulus Ægineta, know positively nothing of this action.

\*\* Gmelin states, in his *General History of Vegetable Poisons* (Nuremberg, 1777), p. 301, that already in 1765 he had noticed mydriasis as one of the symptoms of belladonna-poisoning, but he does not appear to regard this symptom as characteristic, but rather as an incidental one, for, in reviewing all symptoms, he omits this one.

Hamburg. A physician of repute, Dr. Reimarus, had ordered in a drug-store belladonna. The nephew of the apothecary, Johannes Andreas Daries (De Atropa Belladonna, Dissert. Inaug. Auctore Petro Joanne Andrea Daries. Lipsiæ, 1776. Reprinted in Ballinger's Sylloge, vol. ii. p. 58), who prepared the prescription from the fresh plant, had a drop of the juice of the berries, or of the herb, accidentally get into his right eye. Very soon after this accident he was troubled by mydriasis and considerable visual interferences. Reimarus, informed by letter of the druggist's trouble, wrote that he was aware that the ingestion of large quantities of belladonna produced mydriasis, but that he was surprised to learn that the external application of the drug could likewise produce this result. This was, however, Reimarus added, a very interesting matter, and invited decidedly to therapeutic trials of the drug in cataract operations. But even before the arrival of this letter, Daries ascertained, by experiments on a cat, that the fresh juice of the herb and of the berries of belladonna had actually a mydriatic power. Hence Daries is to be designated as the fourth discoverer of the mydriatic action of belladonna.

About the same time, or a little later, Doederlein\* observed in his practice a case recalling that one of Ray mentioned above. A patient having placed a leaf of datura stramonium upon an ulcer near the eye, was soon affected with a complete paralysis of the pupil. Doederlein interpreted this mydriasis very correctly as the action of stramonium, and is accordingly to be regarded as the fifth discoverer of this action. Independently of him, Schiferli,† following the example of his preceptor Loder, who appears to have found the belladonna action for himself, used and recommended in 1796 an infusion of belladonna for cataract extraction. Loder is consequently the sixth discoverer of this action.

After this time the specific action of belladonna upon the eye became generally known in Germany and in other countries.

Thus, we find it mentioned as something generally known in Tromsdorf's Pharmacological Dictionary (Hamburg and Leipzig, 1802, vol. i. p. 299). The action of hyoscyamus

was discovered by Himly in 1800 from botanical deductions, and was warmly recommended for ophthalmological purposes.‡ Ehlers,§ one of his pupils, translated the publication of Himly in question into French, but, either on purpose or by mistake, always wrote belladonna instead of hyoscyamus, inducing thus the French physicians to employ belladonna therapeutically. In the second French edition, however, appearing 1803 in Altona, the word *jusquiam* is used instead of belladonna. In England, Paget|| recommended the belladonna application for cataract extraction.

In lay circles, however, the mydriatic action of the solanaceæ was in the beginning of this century still wholly unknown, and was anew discovered by Runge, the discoverer of the aniline colors. This chemist makes, in his *Chemischen Briefen*,¶ the following interesting communication :

"In Jena I became soon acquainted with Döbereiner, and discussed with him my researches about vegetable poisons, especially the solanaceæ. Döbereiner appeared pleased with the methods instituted by me and the results of my investigations ; he constantly stimulated me to new researches. About this time I met Goethe, at the instigation of Döbereiner, who had told the poet that by experiments upon cats I had found a method of ascertaining with certainty whether or not a poisoning with stramonium had occurred. Goethe had thereupon expressed the desire to meet the young chemist, and to see the demonstration of his discovery. When I crossed the market square in the afternoon, dressed with a borrowed frock coat and stovepipe hat, and carrying the cat under my arm, I created a universal sensation. The boys, who were loitering about the place, at the cry 'Doctor Poison !' suddenly came towards me, and surrounded me. To those joking at my fantastic appearance I said, 'Let me in peace. I am attending to some important business. I am going to Goethe.' I was instantly released. Coming to Goethe's house, I was led

|| London Med. and Phys. Journal, 1801, vi. p. 352; cf. Edinburgh Med. and Surg. Journal, 1813, ix. p. 279.

¶ This book is wholly unobtainable in the book market. A brief abstract of it appeared in the *Pharmac. Handelsblatt*, 1885, p. 23.

\* Conrad Moench, *Lehre von den Arzneimitteln*, Marburg, 1795, p. 337. Moench, by the way, was quite familiar with the publications of Ray and Daries.

† Rud. Abraham Schiferli, *Dissertatio de Cataracta*, Jenæ, 1796; and *Theoretical Practical Treatise on Cataract*, Jena and Leipzig, 1797, p. 85. He was military surgeon, later professor of surgery, and died as such in Bern in 1837.

into the reception-room, and soon stood before the poet. His lofty, handsome, and powerful presence made such an overwhelming impression upon me, that, all in a tremble, I handed him the cat, as if I wanted thus to defend myself. 'Ah! So,' Goethe said, 'that's what is going to be the future terror of the poison-mixers. Just let me look.' I then turned the cat's head so that the light struck both eyes simultaneously, and the difference between the eyes could be readily seen. Goethe was greatly surprised. Alongside of the small slit in one eye, the round great opening in the other presented a very striking difference. In consequence of a somewhat large dose, the entire iris had almost become invisible, thus enhancing this singular aspect. 'How did you obtain this effect?' asked Goethe. 'With hyoscyamus, your excellency,' I answered. 'I have placed the un-mixed juice of the pounded herb in the eye, therefore the action is so strong.' 'Döbereiner told me,' said Goethe, 'that both belladonna and stramonium act alike, and that you have ascertained that the active toxic principle is contained in the plant in all of its parts, from the root to the blossom, fruit, and seed. How is it with other plants, especially those of an affiliated relation?' 'A friend of mine, Dr. Carl Heise, induced by the peculiar action of the stated plants, has shown in an elaborate work that only the plants of the three orders mentioned above affect the pupils in a mydriatic manner. He has tried the action of innumerable other plants on the eye, and found them all to be inert save a few which produced the reverse of mydriasis, viz., a contraction of the pupil, such as aconitum.' 'Well,' Goethe said, 'there is a chance to discover the proper antidote for the toxic action of belladonna. Try this, and apply both antagonistic plants either simultaneously or one after another to the eyes of a cat. Observe the result. The matter is not without difficulties, but you will overcome these. But now, pray tell me, how you came to this peculiar kind of organic chemistry?' Runge related: "In 1810 I was—a pastor's son, from the country near Hamburg—sent to Lübeck, and placed in the Rathsapotheke as an apprentice. It was a warlike time, and Napoleon prepared his invasion of Russia. All men able to carry arms were mustered out, and, on account of the universal unwillingness to serve under the tyrant, it was a matter of difficulty to find a substitute. Through recommendation of my uncle, I had received admission into several aristocratic families, and the son of one of

them became a friend of mine. One evening he came to the drug-store in great commotion, and told me his trouble, that the day after to-morrow he had to present himself for service, and that, being without physical defect, he probably would be taken. 'I would like to mutilate my hand,' he sighed, 'in order not to go into this ignominious war.' 'That is not necessary,' I said. 'Confide in me. I believe to be able to mutilate you for a short time with impunity. They will have to exempt you from service.' 'What are you going to do with me?' 'I will make you blind for twenty-four hours.' 'How are you going to do that?' 'Listen to me. About eight weeks ago I had to prepare a medicine, according to a doctor's prescription, in which a decoction of the juice of hyoscyamus was to be dissolved in water. Preparing the medicine in a mortar, a drop accidentally got into my eye. I experienced no pain, and did not observe any alteration until sensations of light flashes caused me to go to the looking-glass. How great was my astonishment when I saw the change that had taken place in my eye. The iris had almost wholly disappeared, and the eye looked precisely like that of a man suffering from amaurosis. The power of vision was also greatly weakened, as I noticed when I closed the unaffected eye. I don't know why this state of things did not raise any fears in me. After lasting a few days, the abnormal condition disappeared, the power of vision returned, and also the normal proportions of the iris, so that both pupils appeared again of equal size. And behold! such an affection I will produce in both of your eyes, and it would be very queer if you would not be discharged, even after a superficial examination.' After making some easily-removed objections, my friend consented to this at that time very pardonable fraud, and thus saved his life, for of all men that went from Lübeck to the war in Russia but few returned. His temporary blindness lasted thirty-six hours, passed away painlessly, without leaving behind any deleterious results."

Thus far goes the report of Runge, from which we can distinctly see that he obtained the knowledge of the mydriatic action of the solanaceæ by the same accident as Daries derived his knowledge. Runge is consequently the seventh discoverer of this action. He tried even to practically utilize his discovery at once; for he recommended in his dissertation (*De Novo Methodo Veneficium Dijudicandi*, Jenæ, 1819) in a case of suspected atropine intoxication to place a

drop of the urine of the poisoned person into the eye of a cat. The word atropine does not seem to have been known to Runge, for the solanacea alkaloid, isolated approximately by him, he calls koromegyn (Greek, magnifier of pupil). This alkaloid was isolated in 1830 properly by the apothecary Mein,\* of Neustadt-Göders, and independently of him in 1832 by Geiger and Hesse,† while Liebig‡ determined its chemical formula. The solution of the pure sulphate of atropine, instead of the extract of belladonna, was at once used by Geiger§ and Hesse for the purpose of dilating the pupil. The named chemists succeeded soon || after also in isolating hyoscyamine, the active principle of hyoscyamus. They showed that this alkaloid, like atropine, had a distinctly mydriatic action even in a dilution of 1 to 1000.

In the majority of books treating of these historical facts, such as in Hirsch's History of Ophthalmology, and in Hirsch's Latest Discoveries of Materia Medica, Heidelberg and Leipzig, 1843, vol. ii. p. 160, we find the statement that the complete isolation of atropine and hyoscyamus occurred in the first half of the second decade of this century, and was obtained by Brandes and Runge. This, however, is wholly untrue.¶ For all those cases referred only to purified extracts but not to chemically pure alkaloids. After the mydriatic action of the solanaceæ alkaloids was positively made out, and had become generally known, their physiological *modus operandi* had to be determined.

Ernst Heinrich, as early as 1821, stated in his famous paper, *De Motor Iridis* (p. 102), that belladonna paralyzes the nerves of the muscular sphincter iridis. This view was confirmed by the experiments of Biffi (1845), Cramer and Ruiter (1853), and is now held exclusively by all ophthalmologists. Nevertheless, this view is only partially correct, for the most recent students of pharmacology have demonstrated that we have to deal here only with a paralysis of the peripheral ends of the nervus oculo-motorius, while the nervus sympathicus supplying the musculus dilator remains absolutely unaffected.

Fraser, of Edinburgh, discovered in 1861

the only practically applicable medium of pupillary contraction, viz., physostigmine or the extract of Calabar bean. Pilocarpine, muscarine, and nicotine likewise contract the pupil, but this contraction is in intensity and extent far inferior to that produced by physostigmine, and is of little practical importance.

#### A FEW EXPERIMENTS WITH LIQUOR POTASSII ARSENITIS.

BY M. F. WEYMANN, M.D.

AS all the compounds of potassium are claimed to have essentially the same physiological influence on animal tissues, it would, no doubt, be very interesting to assign in the course of this article a special action to the base of the drug. No such attempt, however, has been made, but the medicine simply treated as an independent entity. As for the administration, it was practised *per os*, by injection into the subcutaneous lymph-spaces and into the posterior lymph-hearts directly. All experiments—ten in number—were performed on the frog.

The first signs appearing were unusual activity and restlessness. These, however, abated after the animal had made one or two rounds along the four walls of the room, and were, no doubt, due to the irritation of the local application of the solution. Now a new train of symptoms announced itself by an almost sudden quietude. This quickness of action was, of course, more marked after injection into the lymph-hearts. The batrachian leaped only now and then, remaining in a stupor-like condition between the efforts. The jumping was less energetic, and soon difficulty in controlling the posterior extremities showed itself. Extension was inco-ordinate, and retraction slow and seemingly very labored. The animal now usually got in some corner. Movements became extremely rare. Indifference deepened into stupor. The animal would not only refuse to move on being approached, but even touching failed to elicit any response. After a comparatively short time even painful stimulation was without result. Pinching and striking violently only now and then produced a weak stirring. Still, at larger intervals, the frog made spontaneous movements, by far more perfect than any of those produced by irritation. And what seems even more strange, he would, if placed on his back,

\* Liebig's Annalen, vol. vi. p. 67.

† Ibid., vol. v. p. 38. ‡ Ibid., vol. vi., 1833, p. 66.

§ Ibid., p. 68. || Ibid., vol. vii., 1839, p. 271.

¶ Equally erroneous is the statement that Reisinger (Bayerisch's Annalen; Abhandlungen aus den Gebiete der Chirurgie, Sulzbach, 1827; also *Salzbürger Med. Chir. Zeitung*, 1825, No. 14, p. 237, and No. 15, p. 253) in 1824 had used the pure alkaloids of solanaceæ.

try to regain his original position with a certain readiness generally successful. But even those attempts dwindled into a mere nothing at a time when pretty perfect voluntary movements could yet be observed.

The movements of the heart were greatly accelerated and weakened. Respiration was not notably affected, and this would only be in accord with the fact that in human arsenical poisoning the shallow and hurried respiration is only due to the abdominal tenderness developed from local irritation. Breathing ceased, however, before the circulatory apparatus came to a stand-still. As the doses given were very large, death generally appeared before the lapse of forty-five minutes. This fact may also explain the absence of convulsions in all cases, except a *clonic* shivering in one.

Considering the action of the drug on the tissues *seriatim*, the nervous system claims our first attention.

If a frog be poisoned with the solution, and the vessels of one hind leg tied, the peripheral nerve ends of that member must be exempt from the influence of the poison. Soon the symptoms of paralysis appear. That the latter is not due to a laming of the motor power may be proven by the occasional occurrence of voluntary motion. The paralysis must consequently be induced by sensory inability. If now irritation of the poisoned leg fail to bring about movement, this failure will be just as apparent in the protected leg, although its sensory fibres are intact. This experiment was verified by ligaturing the whole leg, and even severing all except the nervous connection. The result was uniformly the same, therefore sensory paralysis cannot be peripheral. During this stage the motor nerves fully respond to electricity, showing the trunks to be in order. This fact makes it very improbable that the sensory fibres of the same nerve should be killed. Excluding those two possible sources of paralysis, only one—*i.e.*, the spinal cord—is left as the sole cause of the mischief. Its sensory cells are killed, and unable to transform perceptions into motor impulses any longer.

Contrary to the statements of Drs. Murrell and Ringer, motor disturbance was not noted in any case. Galvanization of the nerves promptly resulted in movement. That there was no spinal trouble, or, at least, no complete paralysis, was shown by occasional volitional contractions of the muscles. Still, a certain depressing influence on the motor

cells cannot be denied. The difficulty and perfection accompanying, in the later stages, the execution of its functions, clearly point to that effect. Additional corroborative evidence is afforded by the depression after local applications.

An influence not yet thoroughly appreciated refers, I think, to the cranial nervous centres. All higher functions must be profoundly depressed. The batrachian exhibits no fear on being approached, although our inferences from human poisoning would not warrant the conclusion that disordered vision or blindness prevails. That the centre of co-ordination is very severely impressed is shown by the inco-ordinate movements. Although there is a will and a motor apparatus to execute it, the motor machine lacks that predominating, regulating influence called co-ordination. This is at first only manifested in parts of the system, *viz.*, groups of muscular tissue. Soon, however, the centre even ceases to respond to so profound a stimulation as is afforded by an inverted position, although in the mean time disordered volitional impulses may be observed. If we take into consideration this peculiar influence exerted on the cranial nervous matter, the mysterious action of therapeutic doses of the drug as an alterative would at once be more easily understood, particularly if we are liberal with cranial centres, such as that of nutrition.

That arsenite of potassium works by absorption has been proven repeatedly. Aside from this, it has, however, a local influence. Applied to the heart directly, it first increases the pulse-rate and then diminishes systolic force. If one experiment be sufficient, these phenomena are not to be accounted for by paralysis of the vagi, as galvanization of those nerves produced very visible effects. The main factor seems to be weakness of the heart-muscle. Moreover, this fact is confirmed by a similar behavior of the excised viscus. The whole organ becomes enormously distended, and towards death the contractions resemble a mere shivering. If, however, the ventricular walls be cut, and the cavities so relieved from overdistention, the heart once more becomes regular, only to cease again in a short while. That the resumption of cardiac action is not merely the consequence of the mechanical stimulation of cutting seems very likely, because the muscle would not previously answer to galvanic stimuli. The force gradually is lost, but if a more than proportionate diminution of labor is con-

nected with it (as cutting of the walls certainly is), a *seeming* restoration of force follows. Another proof for weakness of muscular tissue lies with the fact that the ventricles must often rest. Irregularity is sometimes so pronounced that four auricular contractions are followed by one ventricular systole.

In view of these facts, we would very naturally expect to find a sinking of blood-pressure. Experimenters have proven this to be a fact, some adding vaso-motor paralysis to the *status verum*, which would only so much more condition a fall of pressure. Perhaps this action explains, to a certain extent, its *modus operandi* in intermittent fever. Of course, even then we cannot leave out our favorite appellation "alterative."

These deductions show very clearly that the liquor acts very much the same as arsenic, and that the other ingredients (*viz.*, spt. lavend.) have no perceptible influence.

#### THE USE OF MANACA IN RHEUMATISM.

BY F. SPENCER HALSEY, M.D., NEW YORK.

**D**URING the summer of 1885, while House Physician at the Almshouse and Workhouse Hospital, Blackwell's Island, I gave the fluid extract of manaca a thorough trial in many cases of different forms of rheumatism, of which the following serve as type, and indicate the class of case in which manaca may prove of service:

**CASE I.**—Jane S., age 49; native of Scotland; widow. Admitted to hospital May 10 with acute articular rheumatism, affecting chiefly the wrist and knee-joints, which were very tender and swollen. Suffered from slight cough, as she had only a few weeks before recovered from an attack of pneumonia. Was immediately put on a solution of sod. salicyl. of the strength of gr. xv to 3i, of which 3i was given every three hours until its effects were obtained. This was continued for four days, and on May 15 the salicylate was given in gr. xv doses t. i. d. for ten days. Slight improvement, pain less, and joints somewhat less swollen.

**May 26.**—Ordered ol. gaultheriæ, gtt. v t. i. d., and external applications.

**May 28.**—Ol. gaultheriæ increased to gtt. viii t. i. d.

**May 30.**—No change.

**June 2.**—Ordered fld. ext. manaca, gtt. xv t. i. d.

**June 5.**—Complains of tightness around

waist; no marked improvement; joints still much swollen.

**June 10.**—Better; no tightness; swelling slightly decreased; increased manaca to 3ss t. i. d.

**June 15.**—Manaca increased to gtt. xl t. i. d.; swelling considerably decreased; some pain still, especially in wrists.

**June 20.**—Patient up, and walking around; pain very much diminished, and swelling almost entirely gone.

**June 25.**—Manaca given in 3i doses; improvement marked.

**July 1.**—Joints in much better condition than ever before. Patient was discharged from hospital shortly after, being able to get around with little difficulty.

**CASE II.**—Margaret W., age 54; Ireland. Admitted to hospital May 28 with chronic rheumatism, from which she had suffered for over a year. Has had two previous attacks, but not so severe as this. Both wrist and knee-joints, as well as the metacarpal and phalangeal joints of both hands, and the phalangeal joints of both feet affected. Parts swollen and very tender, so that hardly any movement was able to be made. Was immediately put on quinine, gr. ii t. i. d., and manaca, fld. ext. gtt. xxx t. i. d.

**June 1.**—Pain much better; able to move arms a little more freely.

**June 4.**—Motion freer and pain less; manaca increased to gtt. xl, and continued at that.

**June 12.**—Patient up, and walking about the ward very well; very little stiffness.

**June 16.**—Marked improvement. Very good movement of joints, attended with no pain, and treatment continued with tr. ferr. chlor., gtt. x t. i. d.

**June 20.**—Patient discharged, with good result.

**CASE III.**—William E., age 45; Ireland laborer. Admitted to hospital May 1 with chronic rheumatism, affecting his knees and shoulders, which were considerably swollen and motion attended with great pain. Was put on fld. ext. manaca, gtt. xx t. i. d., and external applications of lead and opium was were ordered.

**May 5.**—No improvement; manaca increased to gtt. xxx t. i. d.

**May 8.**—Slight change; manaca increased to gtt. xl t. i. d.; motion freer.

**May 12.**—In same condition; joints swollen very much; was ordered manaca in 3i dose q. four hours.

**May 15.**—Better; can walk a little.

*May 20.*—Pains returned, and patient unable to move; manaca stopped, and ordered sod. salicylate in gr. xv doses q. three hours, under which he improved, and was discharged, being able to walk out of ward very well.

*CASE IV.*—Bernard S., aged 50 years; Germany; laborer. Admitted to hospital June 17 with chronic rheumatism, attacks of which he has had off and on for the past five years. Ordered fld. ext. manaca in doses of gtt. xx t. i. d.

*June 19.*—No change; manaca increased to 3ss t. i. d.

*June 20.*—Slightly improved; can move freer; manaca ordered to be given in gtt. xl doses, with local applications.

*June 22.*—No better; manaca 3i t. i. d.

*June 25.*—Pain in hands and feet worse; unable to sleep; complains of headache and pain in eyes; manaca pushed to 3ii.

*June 27.*—Pain in head worse; dizzy at times; rheumatism no better; manaca stopped, and patient put on ol. gaultheriæ, gtt. v. t. i. d.

*June 29.*—Better; ol. gault. increased to gtt. viii, also used externally in ointment.

*July 1.*—Patient walking about with cane; pain in head gone; swelling of joints less, and more motion. Continued for a week longer, and on July 10 was discharged, greatly improved.

*CASE V.*—Mary E., age 40; United States. Admitted to hospital July 15 suffering from chronic rheumatism of nearly two years' duration. Ordered manaca, 3ss t. i. d., and quinine, gr. ii t. i. d.

*July 18.*—No change; manaca, 3i t. i. d.

*July 21.*—Slight improvement; manaca increased to 3ii t. i. d.

*July 23.*—About the same; ordered manaca in 3iii doses.

*July 25.*—Complains of dizziness and pains in head; joints no better; manaca stopped, and sod. salicyl., gr. xv t. i. d., ordered.

*July 29.*—Better; can get around ward fairly well.

*July 31.*—Patient discharged, time up, in improved condition.

*CASE VI.*—Edward R., aged 56; Ireland. Admitted to hospital August 15. Has suffered from rheumatism, off and on, for the past three years, his feet and hands being chiefly affected. Feet swell up so that he is unable at times to put on his shoes; no kidney nor cardiac trouble; was put on manaca, gtt. xx t. i. d., and tonics.

*August 18.*—Improving; manaca, 3ss.

*August 20.*—Feet better; got shoes on to-

day for the first time in over three weeks; manaca, 3i.

*August 23.*—Improvement continues; pain and swelling entirely gone; manaca, 3iss, ordered, and tr. ferri chlor., gtt. xv t. i. d.

*August 25.*—Same condition.

*August 26.*—Motion freer; joints in better condition; continued treatment.

*August 29.*—Walks around ward with more ease than he has for several weeks; swelling all gone from feet, and general condition greatly improved.

*September 2.*—Discharged; good result.

*CASE VII.*—James W., Englishman; age, 40. Admitted to hospital August 25 with chronic rheumatism in knees, ankles, and wrists. Unable to walk, except with very great difficulty and pain, for over two months. Was put on sod. salicyl., gr. xv t. i. d., and lead and opium wash ordered locally.

*August 28.*—No change; salicylate increased to gr. xx.

*September 1.*—Complains of headache and ringing in ears; joints no better; still suffers much pain; treatment changed, and manaca ordered in 3ss doses.

*September 3.*—Pain less; manaca given in 3i doses.

*September 5.*—Improved; more movement of joints, with less pain and swelling; manaca now given q. i. d. in 3i doses.

*September 8.*—Patient much better; walks with a cane very well.

*September 10.*—Improving daily; put on tr. ferri chlor., gtt. x t. i. d.

*September 12.*—Walked about the ward with no help to-day; swelling entirely gone; very good use of joints.

*September 16.*—Discharged, with exceedingly beneficial results.

#### Résumé of Cases.

Disease.	Sex.	Age.	Amount (Maximum).	Time.	Result.
1. Chr. rheum.	F.	49	3i	52 days.	Good.
2. Chr. rheum.	F.	54	gtt. xl	24 days.	Good.
3. Chr. rheum.	M.	45	3i	21 days.	None.
4. Chr. rheum.	M.	50	3ii	24 days.	None.
5. Chr. rheum.	F.	40	3iii	17 days.	None.
6. Chr. rheum.	M.	56	3iss	19 days.	Good.
7. Chr. rheum.	M.	40	3i	22 days.	Good.

7 cases in all,—4 attended with good results, 3 attended with no results.

## THE THERAPEUTIC VALUE OF ICHTHYOL.

BY DR. JOSEPH SCHMIDT, BERLIN, GERMANY.

(Conclusion.)

IN the first part of this paper I discussed the pharmacal and physiological relations of ichthyol, and alluded to some of the uses which the new remedy had found in dermatological practice. Dr. Unna, of Hamburg, learning that I was writing about ichthyol, kindly placed at my disposal the manuscript of his as yet unpublished "Dermatologische Studien, II.," which, as the most exhaustive existing treatise on the dermatological use of ichthyol, will claim the attention of all specialists. I have to content myself with merely mentioning the principal skin-affections in which ichthyol has proven of high curative value. Of acne, rosacea, and lepra I have spoken before. Eczema, especially the so-called "nervous form" (*i.e.*, depending upon nervous lesions), deserves an especial allusion. Unna emphasizes the striking results obtained in this affection with the simultaneous external and internal employment of ichthyol. The drug proves almost of equal value in lichen urticatus, prurigo, ichthyosis, urticaria, erythema (multiforme and nodosum), zoster, herpes (progenitalis and labialis), and dermatitis herpetiformis.\* In intertrigo the ichthyol ointment is likewise a certain cure, as has been repeatedly observed by myself. In erysipelas and erysipeloid conditions, recently described by Rosenbach, ichthyol in one or another form will likewise give very prompt results. In erysipelas affecting the scalp a twenty to fifty per cent. ichthyol ointment is to be used, and, if the fever be high, together with the ice-bag, although the latter checks the absorption of the remedy. The ichthyol-alcohol-ether spray is, however, a more eligible application, and is to precede the ice-bag. If the erysipelas affects the extremities, Unna recommends the following formula :

R Ammon. sulfo-ichthyolici,  
Spir. ætherei,  $\mathbb{A}$  f3iiss;  
Collodii, f3v. M.

Brush to be inserted in the cork.

In lupus and sykosis, ichthyol can only be regarded as an auxiliary remedy.

In the broad condylomata and keloids our remedy, employed with the brush or in the soap-form, has given moderately good results.

More gratifying is the effect of ichthyol

when applied to the extensive, deep cicatrices of the face, as often seen after smallpox and acne. Daily brushing with a strong ichthyol ointment or the ichthyol collodium will produce a firm mask-like crust on the entire face, which, when falling off, will leave behind a softer skin and more shallow marks. Dr. Schlossberger † has treated in this manner the face of a smallpox patient with an unexpected success.

The value of ichthyol in burns claims the earnest attention of every practitioner. The principal features of this employment are the avoidance of vesication (provided the remedy is applied at once) and the alleviation of pain. In burns of the first degree all symptoms can be removed in a very short time by an immediate application. If burns of a more intense form are partially treated with ichthyol it can be readily seen that the ichthyolized portions *present no vesication*, while the unmedicated places present the typical picture of burns of the second degree. The ichthyol application either removes all morbid symptoms or reduces the burn of the second degree to one of the first degree; pain invariably disappears soon after the application of the drug. Numerous authoritative observers agreeing in the unrivalled value of ichthyol in burns, it is fair to assume that this remedy will replace all other therapeutic measures of a lesser efficacy.

Next to burns, the usefulness of ichthyol is most pronounced in the removal of swellings of a traumatic and rheumatic kind. I have used the drug in about two dozen cases of this kind, and can testify to its remarkable efficacy. The affected parts are to be washed first with lukewarm water (to open the pores), and then the solution is to be applied on a piece of cotton. Thorough rubbing is a greater requisite than the application of a large quantity of the drug. After the application the parts are to be dressed in the ordinary manner; in rheumatism with cotton, preferably. One application pro die is usually sufficient, provided the drug is well rubbed into the parts. Pain and swelling invariably yield to the drug, and a couple of days suffice in most instances to eliminate all morbid symptoms. In two cases of a rheumatic swelling of the ankle-joints, a single application followed by a cotton dressing removed pain and swelling on the third day.

It is claimed that the drug is a specific anti-rheumatic of the highest value, and that its

\* Quite recently described by Prof. Duhring, of the University of Pennsylvania.

† On board steamship "Polynesia."

greatest efficacy in rheumatism is obtained from its combined external and internal application. Having no personal experience with the internal administration of ichthyol in rheumatism, I refrain from expressing any opinion on this point, though it is true that Prof. Schweninger, of Berlin, in a letter addressed to the Ichthyol Company of Hamburg, states that in his experience "ichthyol is an anti-rheumatic of the first rank," and that Prince Bismarck has permitted him to announce that the preparations of ichthyol have invariably given him the promptest relief in rheumatism, *ischias*, lumbago, and contusions.

It is clear that a recommendation coming from such a source must go far—in Germany, at least—in popularizing the new remedy.

The applicability of ichthyol is so extensive that, although having discussed its uses in very many affections, there are still some remaining which demand an allusion.

The drug possesses pronounced styptic qualities, and is consequently useful in all hemorrhages and wounds. The ichthyol plaster which I have tried gave better results than any other medicinal plaster used in cuts and wounds. The sticking quality of the ichthyol plaster is so intense that it does not fall off the part even when being washed.

In conclusion, I can state that even in toothache ichthyol has in my hands sustained its character of a prompt relief-bringing remedy. A drop or two of a combination of ichthyol and chloroform (one to three) placed on a piece of cotton in the hollow of the tooth, or rubbed into the adjacent gum, is certain to bring almost instantaneous relief.

I have no doubt that this new remedy, endowed with the highest of healing powers, will find a fair trial with the American practitioners, and will in time become as popular in America as it is in Europe.

---

*SOME REMARKS ON THE TREATMENT  
OF THE SUMMER GASTRO-INTESTINAL  
DISEASES OF CHILDHOOD.*

---

BY J. H. MUSSER, M.D., PHILADELPHIA.

---

THE outlines of treatment herein indicated have been so eminently satisfactory to the writer during the past four years that it was thought they would be of interest to the profession. No claims to originality are made for the methods, and doubtless the reader will observe only a repetition of what has been said before. Their repetition is ventured upon,

however, because of their great value in the writer's experience. The essential to success is the selection and pursuit of a systemic plan of treatment in cases of summer intestinal disorders. This, above all, is insisted upon.

The summer disorders of childhood are vomiting (acute and chronic indigestion), simple diarrhœa, entero-colitis, and cholera infantum. Vomiting and simple diarrhœa often are present in the same subject and due to the same causes. The causes in general of all these complaints are extreme heat, improper food, atmospheric changes (cold and dampness), a vitiated atmosphere, and reflex irritation from teething, etc. One or more of these causes preponderates in the respective affections. Their universal presence in various degrees in all the complaints renders it necessary to base a treatment of the ailment on a removal or counter-action of these general evil influences. What should be done is patent, and therefore, bearing this in mind, the outlines of treatment will be presented. The management common to all these affections will be detailed, and then some few remarks made on the therapeutics of the individual affections.

GENERAL MANAGEMENT OF THE SUMMER  
GASTRO-INTESTINAL DISEASES.

*Diet.*—The simplest and blandest articles of nourishment are ordered. In an acute case, as acute vomiting or cholera infantum, the child is taken from the breast, or the usual milk or artificial food is removed, and weak rice-water or barley-water given. The happiest results are often seen in the use of these simple means for twenty-four or forty-eight hours. In cholera infantum, brandy alone well diluted is used if the rice-water is not retained or the stage of collapse is imminent. In fact, for twenty-four or forty-eight hours, brandy, sometimes in incredible doses, is given. Five to twenty and thirty drops every half-hour or hour are frequently ordered. After the stomach has regained its strength, stronger nourishment may be used. Four things are relied on,—1. Cream, a teaspoonful to three ounces of warmed water every hour or two, gradually increasing the strength; 2. Milk, peptonized according to the Fairchild method; 3. The well-known gelatin, cream and milk preparation, recommended by Meigs and Pepper; 4. weak chicken-broth. In the more chronic summer ailments this dietary may be resorted to alone. Flour, boiled and baked in a bag until very hard, grated fine and added to milk, is of great service. Not much confi-

dence is placed by the writer in the artificial foods or condensed milk. They are of inestimable value under circumstances which prevent the preparation of the above articles. A careful mother, it always seemed to the writer, can supply from her own kitchen the foods which are heralded forth with so much mystery. The suggestions of Keating, Meigs, and many others give timely aid to the anxious mother in the making of foods. It is true, if the parent does not have a refrigerator to keep the milk, and other essential utensils, or the simple knowledge to cook properly, condensed milk or some "infant's food" are necessary.

*Bathing.*—Bathing is used to reduce the temperature, for derivative purposes, and for the sake of cleanliness. Children in close quarters during the hot weather, with even an ordinary gastro-intestinal affection, are ordered to be bathed in warm or tepid water every two hours, and encouraged to remain in the bath some time. Certain cases of cholera infantum, presenting cerebral symptoms not unlike thermic fever, have hyperpyrexia, due to excessive heat. To reduce the temperature is important. Cloths wrung out of ice-water and applied to the head, spine, and abdomen may suffice. Careful spongings with water and alcohol are of eminent service. Cold baths, the patient being placed in a bath at 100°, reducing gradually to 60°, are at times necessary. It has not been the writer's lot to resort to this method often. It is our only hope in some cases, however. For derivative purposes the general warm bath is used. It should be used, if there is fever, irritability, and sufficient strength, two or three times daily. If there is much exhaustion, the baths for cleanliness should be made stimulating by the addition of salt, whiskey, or alcohol. Sea-salt has been of service.

*External Derivatives.*—They are important. A weak mustard-plaster, the familiar spice-plaster, or flannel dipped in Jamaica ginger (3i) in hot water (3iii), applied to the abdomen, may be used. Hot foot-baths and mustard foot-baths are of great value. If there is fever and irritability, frequent foot-baths are ordered, and their good action is manifest in quieting the perturbed nervous system. It is of prime importance to keep the abdomen protected. When the stimulating applications are not used, warmed flannel, well fitting, is kept on. The extremities, too, must be protected. Long stockings should be worn, or the feet otherwise clad. In entero-colitis and

chronic diarrhoea these precautions are almost essential to successful management.

*Inunctions.*—They are of extreme value, and have saved life in many of the writer's cases. Not only is the absorption of the oil of service, but, doubtless, by the gentle manipulation, all the advantages of massage are secured. In the acute or subacute affections, without fever, inunctions are begun at once. In the stage of extreme prostration after cholera infantum, or in the marasmic state that is so liable to ensue, its effects are often magical. Cases of indigestion (chronic vomiting) respond rapidly to this form of nourishment. Inunctions are especially indicated in every case in which there is gradual but palpable failure in strength and loss of flesh. In fact, it may be said, in every case of summer affections, either baths or oil inunctions are used by the writer, and the latter in all cases in which the former is not more strongly indicated. The only possible exception to this is in cases of sthenic entero-colitis, but if there is much debility following, inunctions are ordered. In many cases the baths and inunctions are used, the baths until the acute febrile symptoms have subsided, the inunctions subsequently. The writer orders cod-liver oil once or twice daily, gently rubbed in, and every second day a cleansing bath of alcohol and water. It is of advantage sometimes to anoint with oil at night, and use the cleansing bath in the morning.

*Stimulants.*—But little need be said of stimulants. They are indicated on general principles, and are of great service not only in cholera infantum, as previously indicated, but in other affections. In gastric affections, a good claret or sherry or whiskey are the best. In diarrhoea, burnt brandy, port, or some astringent cordials, as home-made blackberry wine, may replace the others.

#### MEDICINAL TREATMENT OF THE SUMMER GASTRO-INTESTINAL DISEASES.

While important, the writer is disposed to think its value is secondary to that of the hygienic management. Certain it is that more cases will get well with the management indicated above without medicines than with medicines and a disregard for hygienic and dietetic principles. The selection of remedies is usually based by most practitioners on the symptoms. Theories of the nature of the disease guide others, and, if they were based on facts, would be the true indications for rational treatment. The theory of the ptomaines is becoming more and more a reality, and

if it is proven as the basis of many intestinal disorders, our treatment must be carried on in accordance with such views. Granting it, the plan to pursue is to prevent abnormal decomposition of ingesta in the stomach, to prevent abnormal decomposition in the intestines, to remove the products of decomposition, and to antagonize their action. We are not sufficiently familiar with the physiological, or rather pathological, action of ptomaines to be able to counteract their evil influence by medicines. Much work is being done, however, and light will soon be given us. The prevention of the decomposition of ingesta and intestinal products is, we submit, effected by the selection of a proper diet. It will be seen further that calomel is a most important therapeutic agent, and what empiricism has taught we now learn from scientific experiment to be correct. No doubt the antiputrefactive power of calomel is one most important reason of its great value. Again, to remove the products of decomposition, we have in calomel a reliable agent; other remedies of a purgative or laxative nature have their place. The subsequent suggestions are made from clinical experience, and are given devoid of theory.

*Vomiting, Acute.*—Calomel, in small, frequently-repeated doses, is one of the best sedatives. One-eighth to one-twentieth of a grain every half-hour is ordered.\* If there is fever, pain, or great restlessness, one-twelfth to one-fourth of a grain of Dover's powder may be added.† The value of the drugs is enhanced and their efficacy rendered possible only by the small size and very frequent repetition of the dose. The writer places most reliance in the calomel and Dover's powder combination. Often, in simple cases of vomiting, lime-water and whiskey are of service. For the more chronic forms of vomiting, with calomel subnitrate of bismuth is ordered; lacto-peptine, or saccharated pepsin, is often used. In some obstinate cases of vomiting my friend Dr. Gittings told the writer he has used a decoction of peach-leaves with success. He has the fresh leaves gathered, and a small handful steeped in boiling water (Oss). The

water is decanted, and used freely. The writer's personal experience accords with the above. Again, a weak acid mixture, as the acid solution of pepsin devised by Schaeffer, has been of service in many of my cases. These have been cases of feeble digestion; an atonic state of the system as well as the stomach being obvious. The glycerin in the preparation may be of advantage in preventing putrefaction in these cases. The general management above indicated is all-important.

*Simple Diarrhœa.*—The simple astringents, the familiar antacids, the occasional use of rhubarb with an antacid, generally suffice. Jardinella's syrup, or the fluid extract of blackberry, is of great value alone or combined with other astringents. In the protracted or chronic forms, nitrate of silver in solution is of great service. Carbolic acid with bismuth, where bismuth alone failed, has been of value.

A warm abdomen and warm feet are important, as well as a proper diet and good hygiene.

*Entero-colitis.*—With external stimulating applications and care in diet much can be done, but some medicines must be used. These agents are resorted to,—castor oil and laudanum, rhubarb and laudanum, or quinine and calomel.

The writer usually commences at once with mist. olei ricini and laudanum, administering a dose every two hours‡ until the tormina and tenesmus are relieved and the blood and mucus flux checked. If a rhubarb mixture be used, either the sweet tincture or the spiced syrup are the best preparations. In some obstinate cases, or cases complicated with malaria, or in malarious regions, quinine, in powder or syrup, alternating with small doses of calomel and Dover's powder, is essential. As soon as the passages are free from mucus and blood, the tenesmus relieved, astringents and tonics replace the above. The writer has the notes of seven cases of entero-colitis treated with creasote with excellent effect, two resisting all other treatment previously.

*Cholera Infantum.*—A very successful run of cases treated by the very frequent use of Dover's powder and calomel, in small doses, dry on the tongue, has made the writer rely chiefly on these drugs. Stimulants, of course, are used. The prescription of morphine and

sulphuric acid, long ago advised by Meigs, is one that often checks vomiting, yet so often has the writer been disappointed, all medicine being rejected, that he resorts to placing the powders mentioned above on the tongue. They are so minute that they are readily taken into the pharynx, and the water or stimulant washes them down. If the child sleeps, the powders are not given so frequently. The writer has not had the misfortune to see the stage of collapse ensue in cholera infantum since instituting the above plans of treatment. He sorrowfully admits that he has never had any cases to recover from the cholera collapse. After the more acute symptoms of cholera infantum are controlled, tonics and astringents are used.

The writer's experience with small enemas, containing astringents and opiates, has been extremely unsatisfactory. He failed to see any benefit that could not be accounted for by the other drugs.

It is to be remarked, finally, that these methods of treatment are not to replace the removal of the sick patient to the sea-shore or mountains. They are especially for the unfortunates who cannot be removed from the depressing influences of the heat, bad air, and generally unhygienic surroundings.

#### NOTES FROM GENERAL PRACTICE.

BY FRANCIS L. HAYNES, M.D.

##### I. COCAINE-SPRAY IN EPISTAXIS, AND IN NASAL SURGERY GENERALLY.

**I.** A., aged 20, suffering from a severe attack of typhoid, was troubled by frequent epistaxis. The attacks were invariably relieved by throwing into the nostrils, for a few moments, spray from a two per cent. solution of cocaine. On one occasion, copious bleeding was allowed to persist for three hours, when the spray checked it immediately. Until the patient convalesced, the spray was needed almost daily, and frequently several times a day, but the nurse never allowed more than a few drops of blood to be lost.

Four per cent. solutions of cocaine, applied freely as a spray, are efficient in preventing pain from slighter manipulations, such as the removal of gelatinous polypi. Before more severe operations, in addition to the use of a four per cent. solution by the spray, a ten per

cent. solution should be accurately applied on one or more pledgets of absorbent cotton to all surfaces about to be treated, and kept in position for ten minutes. Where this is impossible, a ten per cent. spray may be used, placing the tip of the atomizer as near the seat of the disease as may be. With these precautions, I have made an incision through the whole length of the cartilaginous septum, and transfixed with Roberts' pin, the patient declaring the procedure to be painless. Operations under cocaine are attended with but little hemorrhage, thus contrasting remarkably with those performed under ether-anæsthesia.

The facility with which some of the more remote portions of the nasal cavities may be examined and treated, after the complete shrinkage of the erectile tissues produced by cocaine, needs but to be mentioned here.

*Cocaine is as essential to a thorough examination of the nose as a mydriatic to that of the eye.*

The spray, from the rapidity and diffuseness of its action, is undoubtedly the best method of applying the drug, for this and for many other purposes.

An atomizer made by the Davol Company ("Magic, No. 25"), I have found very useful in operations upon the pharynx and nasal passages.

##### HIMROD'S ASTHMA CURE.

This proprietary medicine, which has attained a certain reputation in the treatment of asthma, is said to consist of a mixture of coarsely-ground stramonium-leaves and lavender-flowers with a little benzoin, the whole sprinkled with sufficient of a saturated solution of nitrate and chlorate of potassium to make the powder burn well. Another formula consists of equal weights of powdered lobelia, stramonium, black tea, and nitrate of potassium, well mixed and sifted. DR. MORELL MACKENZIE, quoting the last formula, recommends the addition of a little aniseed or fennel. A French formula advises stramonium and sage. The foregoing may or may not be identical with the proprietary article, but in any case they share with it the power of alleviating and cutting short the troublesome attacks to which sufferers from asthma are liable. It is an unsatisfactory feature of even the best remedies that they ultimately fail to produce the relief which first attended their use.—*Med. Press and Circular*, May 26, 1886.

### NITROMURIATIC ACID AND MELANCHOLIA.

It will possibly be remembered by our readers that we published some months ago a lecture by Dr. H. C. Wood upon Melancholia, in which the relations of the disorder with oxaluria were incidentally discussed, with the conclusion that there are two sets of cases in which there is emotional depression associated with oxaluria. In the one set the administration of nitromuriatic acid causes both the oxaluria and the melancholic feelings to disappear, while in the other set the remedy does not affect either condition. The author further called attention to the need of the study of the urine by those who in asylums meet with insane patients in numbers. This lecture has called forth a very interesting article by Dr. G. D. Stahley in the *Medical News* for June 5, in which the results of the examination of the urine of 172 patients for the oxalates are given as follows:

"Mania, 72; melancholia, 38; dementia, 41; paresis, 18; imbecile, 3. Of these 172 admitted, 32, or 18.6 per cent., showed the presence of oxalate of calcium in their urine. Dividing these cases into their respective groups,

we have the following: In the 72 cases of mania we find the presence of crystals of calcium oxalate in 13, equal to 18 per cent.; in 38 cases of melancholia we find 7, equal to 18.4 per cent.; in 41 cases of dementia, 10, or 25 per cent.; in 18 cases of paresis, 2, or 11.1 per cent.; the remaining 3 cases were imbeciles, and their urine contained no oxalates. A summary of these places dementia at the head of the list with 25 per cent.; then melancholia, 18.4 per cent.; then mania, 18 per cent.; then paresis, 11.1 per cent.; and on the whole number, a percentage of 18.6."

"It appears from this showing, that if oxaluria is to be considered symptomatic of any form of mental derangement, the priority must be given to dementia and not to melancholia. It will be observed that melancholia, with its 18.4 per cent., falls somewhat short of being up to the average on the whole number, which is 18.6 per cent. In regard to the quantity of the oxalate present in each case, the examination notes credit two cases of mania and one of paresis, with an 'abundance,' and all the remaining ones are marked 'a few,' meaning the presence of one, two, or three crystals at most in each microscopic field. Of these two cases of mania, one was of the subacute form, with delusions of suspicion, and produced by alcoholic excesses; the other was an acute case, and characterized by mental confusion, restlessness, and homicidal impulses; the case of paresis was typical of that form of insanity."

"It was noticed that, on admission, oxaluria existed in 32 of these cases. Up to the present time, 15 of these have been discharged, and 17 still remain in the house. Of the 15 discharged, it is not known whether the oxaluria had disappeared or not, as no analysis was made previous to their departure. The 17 cases which still remain are divided in type as follows: Mania, 7; melancholia, 3; dementia, 6; and paresis, 1. Of the 7 cases of mania, in 3 the oxalate of calcium has disappeared from their urine; their mental condition has not improved since their admission, and we do not expect them to recover. The remaining 4 cases still exhibit some oxaluria, of which number, only one, a case of acute religious mania, admitted the last week in February, we hope to restore. Of the 3 cases of melancholia, the oxalates have disappeared in all; 1 of them is convalescent, and the other 2 present a very unfavorable prognosis. Of the 6 cases of dementia, there is an absence of oxaluria in 5, and in neither is there

the remotest chance for recovery. The sixth case, complicated with epilepsy, still contains some crystals, and presents no favorable symptoms. In the case of paresis, some calcium oxalate still remains; his prognosis is the customary one in such cases. Thus, it appears that in a total of 11 cases in which oxaluria had been present on admission, but subsequently disappeared, only 1 case is convalescent. And in a total of 6 cases in which oxaluria existed on admission, and still continues, only 1 case has any reasonable prospect of recovery."

These results are exceedingly interesting and valuable, but they do not prove, as Dr. Stahley seems to think, that there is no relation between mental depression, oxaluria, and nitromuriatic acid. Oxaluria may exist without mental depression; mental depression may exist without oxaluria; oxaluria may exist without melancholia; oxaluria and mental depression may coexist and have no relations with nitromuriatic acid; and yet there may be a form of mental depression and oxaluria having very direct therapeutic relations with nitromuriatic acid. Headache may exist without strabismus, strabismus may exist without headache; headache and acute strabismus may coexist without having any therapeutic relations with iodide of potassium, and yet the coexistence of headache and strabismus ought always to suggest the use of iodide, and often is cured by such use.

We suppose that every physician in private practice must have seen numerous cases of depression of spirits, varying in intensity, in which the oxalate of calcium does exist in the urine, and is removed by the use of nitromuriatic acid with the relief of the depression. The fact that often the oxaluria can be removed by vacation and exercise is also no proof that it cannot also be cured by nitromuriatic acid.

The relation between mental depression, oxaluria, and nitromuriatic acid is no new thing. The writer well remembers it being distinctly taught during his student life at the University of Pennsylvania a quarter of a century ago, and his own glee before graduation at the success of his application of the teaching to the case of a fellow-student. The most that can be with any degree of propriety claimed for the facts of Dr. Stahley is that they indicate that in the graver forms of insanity that are met with in asylums the oxaluria is an accident of the disease not etiologically connected with the emotional condition. He is also probably correct in be-

lieving that under these circumstances the oxaluria is frequently due to derangement of the digestive organs.

Some of the arguments of Dr. Stahley seem to us of importance, as leading up to certain conclusions, to which we have been in the last few years more and more drifting, namely, that the so-called diseases of insanity are not diseases at all, or, in other words, that melancholia, mania, and similar so-called diseases are simply symptom-groups, and that until this is recognized there can be little clear thinking about insanity. The paragraph which we have referred to reads as follows:

"And, when we find cases of melancholia associated with oxaluria, let us not be guilty of perpetrating an irrational division of the disease into two varieties, based on the fact that in the one case nitromuriatic acid dissipates both the diathesis and the disease, and that in the other it does neither. Such a division is most irrelevant and unscientific. As well divide all headaches into two varieties,—the first constituting those which are relieved by inhalations from the family camphor-bottle, and the second, those which are not influenced by this procedure."

Possibly Dr. Stahley, when age shall have cooled his youthful impetuosity, will learn that in friendly discussion of scientific questions nothing is gained by asserting that those who differ from oneself are guilty of perpetrating irrational acts, but his paragraph is an exceedingly useful one, as enabling us to illustrate the meaning probably intended by our contributor, and also some ideas which will perhaps meet with no more favor from Dr. Stahley than did oxaluria.

The paragraph seems to us to illustrate very clearly the confusion of thought which grows out of considering a symptom-group to be a disease. The modern scientific physician knows headache is not a disease, but if he finds clinically that a certain headache, characterized by the presence of a certain substance in the urine, is relieved by a certain remedy, he does not hesitate, for practical purposes, to separate that group of headaches from other headaches. Now, melancholia so called is not a disease at all, but, like headache, is a symptom, or a symptom-group, and it is practically important to distinguish groups of cases to be recognized by association of the melancholia with other symptoms relieved and having peculiar relations with remedies. In old times the neurologists spoke of hemiplegia as a disease, and to-day we know that hemiplegia is a symptom which may de-

pend upon a great variety of causes. The pathology of insanity is so utterly recondite and so little understood, that symptom-groups are almost the only thing we can at present recognize. Scarcely two writers upon insanity can be found to acknowledge the existence of the same so-called diseases, much less to define them similarly, or to group them in like manner. The classification of the forms of insanity seems to be utterly hopeless, probably because we know nothing whatsoever of the diseases which afflict the mental functions, and substitute for such diseases the symptom-groups already spoken of. If melancholia, mania, etc., are diseases, we must consider that distinct diseases are based upon the same brain-lesion, for it is well known that in general paralysis of the insane the sufferer may be profoundly melancholic, may be wildly maniacal, or may in contented quiet nurse his delusions of grandeur.

#### *THE LOCAL ANÆSTHETIC ACTION OF BRUCINE AND THEINE.*

NO other department of the whole province of pharmacology has been more thoroughly and successfully studied during the last two years than that of local anæsthesia. The discovery of the now famous anæsthetic property of cocaine has furnished the praiseworthy stimulus to the efforts which have been put forward in search of the same property in other therapeutic agents. And the strangest feature of this whole investigation exists in the fact that none of the substances which have been shown to possess the power of local anæsthesia are of recent discovery, but all were believed to have their well-defined places in the works on *materia medica*, and some of them were known to the profession for hundreds of years.

About a year ago there appeared an article in this journal (see *THERAPEUTIC GAZETTE*, June 15, 1885) on the "Physiological and Clinical Action of Brucine," by Dr. Thomas J. Mays, of Philadelphia, in which he shows that, physiologically, brucine has a specific affinity for the nerves of sensation, and that it produces local anæsthesia both in animals and man when applied to the surface of the body. It was found that a five or ten per cent. solution of the drug completely relieved the scalding on the lip and tongue produced by Cayenne pepper, as well as the itching produced by croton oil, and the burning caused by a mustard-plaster. It also gave surprising

relief to several cases of pronounced chronic pruritus. Its power of relieving perverse itching in any part of the cutaneous surface, especially in pruritus of the anus and vulva, has been confirmed by the clinical experience of the writer in a number of cases of this kind. Dr. Charles H. Burnett, in a paper read before the American Otological Society, July 12, 1885 (*Trans. of Amer. Otolog. Soc.*, 1885), attests the inefficiency of cocaine applications to the ear, but reports excellent results from the application of a five per cent. solution of brucine to the same. He states that "the relief to pain has been prompt and complete, a result far more satisfactory than any obtained by using cocaine solution." He applied it by means of a cotton mop. Dr. Ralph W. Seiss, of Philadelphia, contributes some interesting notes of quite an extended experience with brucine in the *THERAPEUTIC GAZETTE* for January 15, 1886. He employed it in painful furuncles of the external auditory canal, in suppurative otitis, in sensitive conditions of the auditory canal for the purpose of rendering the use of instruments painless, and of lessening or abolishing the pain and burning caused by applications of iodine, nitrate of silver, sulphate of copper, and the like to the mucous membranes of the throat and nasal passages, and witnessed marked relief in the great majority of instances. Although more permanent in its effects, he does not believe it to be as reliable as cocaine.

Although the action of brucine never obtained much scientific investigation, it was always taken for granted that, like its twin-sister, strychnine, it almost exclusively affected the motor division of the spinal nervous system; yet the experimental and clinical data referred to render it very certain that either a notable difference exists between the action of these two agents, or that all our physiological and clinical knowledge of the action of strychnine rests upon an insecure foundation.

But one of the most remarkable of all the local analgesics which has been brought before the profession is theine, the alkaloid of Chinese tea. Attention was also first drawn to this agent by Dr. Mays in an article on "The Physiological and Therapeutic Action of Caffeine, Theine, and Guaranine," which appeared in the *THERAPEUTIC GAZETTE* for September 15, 1885. It was here shown, from experiments made on frogs, that theine paralyzes the nerves of sensation; and that this impairment of sensibility proceeds from the centre to the periphery, and not, like that of brucine, from the periphery to the centre.

Subsequent investigations by the same author, which were published in the *Medical News* for December 12, 1885, and April 17, 1886, proved that it exerts the same influence on man. In the two last-mentioned articles the author contributes the clinical results derived from thirty-nine cases of painful affections in which it was employed by himself and by some of his colleagues, and it appears that the verdict is almost unanimous in favor of its usefulness, not only in affording immediate relief to the pain, but also in effecting a cure in many of the cases. The special nature of pain in these cases consisted of neuralgia, chiefly of the sciatic, intercostal, and cervico-brachial variety, lumbago, myalgia, rheumatic pain, etc., in which from one-half to two and a half grains of the alkaloid were introduced subcutaneously at or near the central origin of pain.

Among the extraordinary features in the action of theine is its localized anæsthesia below the seat of injection. There can be no question about its general absorption; but there has occurred no evidence in the author's experience to show that it produces any systemic disturbance, even in maximum doses. Its absorption and distribution by the blood probably play a secondary rôle, for it seems to exert its influence on the trunk of the nerve at the point of its injection, and then to distribute itself downward along its course in spite of these functions. This localized action of theine naturally gives it an immense advantage over morphine, atropine, chloral, and other agents of that class, which principally act by intoxicating the central nervous system.

Theine also appears to be very prompt in its anæsthetic action. The writer has on a number of occasions witnessed patients suffering from the most excruciating neuralgic pains, who were entirely relieved in less than five minutes. It is also very rare to find the pain returning in less than ten or twelve hours, and oftener not until in twenty-four hours, and then very probably not in its original intensity.

Evidence from other sources than those above quoted convinces us that theine has a wide scope of application, and that it bids fair to play a most prominent part in the therapeutic relief of pain. We, therefore, await with much concern further developments in the use of this interesting drug.

Now a few words to those who never weary of asserting the utter worthlessness of experimental therapeutics to practical medicine. It is very clear, of course, that such dogmatism

only springs from insufficient scientific training, combined, probably, with a desire of truckling to that popular prejudice which every new science encounters. It is evident, too, that in the end such pedantic efforts will prove to be as harmless as the kick which Sam Weller administered to the fat boy when he undertook to express admiration for the pretty cook: there can be no doubt, however, but that they exert a mischievous influence on the formative period of public opinion on this question at the present time. It is noteworthy, therefore, that in brucine and theine we have two more agents added to our list of remedies, which have been given by experimental to practical medicine. Brucine was isolated in 1819, and, until the appearance of Dr. Mays' article, its action was regarded as being analogous to that of strychnine. So, also, in the case of Chinese tea. The leaf of this plant has formed a domestic drink for many centuries, and its alkaloid theine has been known for nearly threescore years; yet no one suspected that the latter contained an analgesic action more remarkable than that of cocaine until it was discovered by the crucial test of scientific experiment, and that on the frog alone.

#### THE PREVENTIVE INOCULATION OF YELLOW FEVER.

AS is well known, Dr. Freire claims that he has discovered a means of preventing yellow fever through inoculation by transferring the supposed germ of yellow fever through animals that possess the requisite receptivity.

His inoculations now are said to reach nearly seven thousand, and, according to the testimony of Dr. H. M. Lane, who states that he was able to follow up a large number of the inoculations reported, of these he was unable to find a single well-authenticated case of an inoculated person dying of yellow fever; but he found numerous instances of death from yellow fever among persons not inoculated living in the same yard, sometimes in the same house, with persons who had contracted this disease. Dr. Lane's testimony is of especial interest, as he himself submitted to the preventive inoculation, and he reports the details of the operation and its results in *The Boston Med. and Surg. Journ.*, June 10, 1886. Dr. Lane states that he arrived in Rio on the 16th of March last, during the prevalence of an epidemic of yellow fever. The next morning Dr. Freire

at eleven o'clock injected into his left deltoid 16 minims of his pure culture of the yellow fever germ of the twenty-second attenuation. At 5 P.M. he had a slight chill, followed by a feeling of general discomfort, nausea, frontal headache, pain in legs and lumbar region, the temperature going up with corresponding acceleration of pulse until 2 A.M., when it reached 102.7°. At this time he fell asleep, and slept for two hours, when he awoke perspiring. The pulse and temperature gradually declined until 7 P.M., when they had reached normal. The headache and other symptoms also left him feeling a little weaker than usual, without appetite, with a furred tongue, and skin slightly jaundiced. There was an almost complete suppression of urine for almost twenty-four hours. The restlessness, the hot dry skin, the thirst, nausea, headache, and muscular pain were all characteristic of the first period of yellow fever. During the next week he was constantly exposed to the disease in the affected districts, and came in contact with yellow fever patients without further trouble, while a friend, coming with him from the same place as himself a few weeks before, and passing a single night in Rio, had taken the yellow fever and died.

Of course the escape of a single subject of inoculation from yellow fever is of little value, but taken together with the seven thousand inoculations which also have been claimed in each case to have prevented the disease, the escape is too marked to have been a mere coincidence.

In a report as to the results obtained by Dr. Freire made to the Société de Biologie de Paris at a recent meeting, M. Rebourgeon stated that of 3051 subjects inoculated at Rio not one had died, whereas, in the same districts and houses, 278 non-vaccinated persons had succumbed to this disease. It is even claimed that when the inoculations are practised in the second stage of severe cases of this disease, recovery will almost invariably result. M. Rebourgeon stated that he had frequently inoculated himself with attenuated virus, and was so convinced of its protective power that he had exposed himself without hesitation to the disease, and he even offered to undergo inoculation with the yellow fever itself. He presented a specimen of the attenuated virus to the Society for examination, and a commission consisting of Brown-Séquard, Cornil, Duval, Bourquelot, and Maurel, were appointed to study the method and value of these inoculations.

We believe that there is at present a bill be-

fore Congress which has for its object the investigation of the truth or falsity of the claim advanced by Dr. Freire as to his power of preventing yellow fever. If this is so, we can only hope that it will pass, and the subject be disposed of one way or the other.

#### SULPHATE OF SPARTEINE.

**I**N the sarothamnus scoparius are two bodies, sparteine and scoparine, which were both discovered in 1851 by Stenhouse. It was not, however, until 1879 that the medicinal properties of one of these alkaloids, sparteine, first attracted attention, although the genus to which these plants belong had long been known to possess diuretic properties.

Of these two substances, sparteine has attracted the most attention. Sparteine ( $C_{15}H_{22}N_2$ ) is an alkaloid, which, in its pure and fresh condition, is an almost colorless, oily fluid, but which, through the action of light and the atmosphere, soon becomes colored brown. It gives all the characteristic alkaloidal reactions, and forms crystallizable salts, which are soluble in water. Of these, the sulphate is most readily soluble, and is the one which is most ordinarily met in the market. Sparteine is heavier than water; boils at 278° C., and has a rather pungent odor, recalling that of pyridine, with a very bitter taste. We have already, in a previous issue, described the methods for its isolation. Sparteine is not the diuretic principle of scoparius, but is an alkaloid which, according to Fick, Laborde, and Germain-Sée, when injected hypodermically in rabbits in doses of about 1 grain, produces increase of the pulse and the respiratory frequency, frequent disturbance of co-ordination and somnolence, and finally death, with convulsions, through paralysis of the spinal cord and inhibitory centres of the heart.

According to the researches of Mitchell and Schroff, sparteine is fatal to rabbits in the dose of 1 drop. Fick was the first to observe the paralysis of the pneumogastric produced by this alkaloid (*Archiv für Experimentale Path.*, Bd. i., p. 397), while he also noticed with it increased diuresis. In 1880, Raymond, in Vulpian's laboratory, made some experiments with sparteine, but he does not appear to have noticed its action on the heart. This action has been principally emphasized by the more recent researches of Laborde and Sée. Laborde (*Tribune Médicale*, November, 1885), from a number of ex-

periments made with the sulphate of sparteine, obtained by the method of Houdé, on rabbits, dogs, and frogs, claimed that sparteine increased the intensity and duration of the cardiac contraction apparently through a central action, and that in frogs, after cessation of respiration, the heart persisted in its rhythmical contractions. Sée has employed sparteine in therapeutics as a substitute for digitalis, and claims that while free from the disagreeable and dangerous after-action of digitalis, it increases the power of both the heart and pulse more strikingly even than digitalis or convallaria. When the heart is disturbed in its action, as in typhoid states and febrile conditions, sparteine is said to raise the vital energy of the entire organism and to regulate the pulsations of the heart. Sée has, however, never noticed any increase of the urinary secretion under its influence, a fact which seems almost inexplicable in the face of the enthusiastic statements which he makes as to its power of increasing the force of the ventricular contraction. According to Sée, sparteine is indicated when the pulse is feeble, irregular, or intermittent, and where, from some other reason, digitalis or the other cardiac stimulants are contraindicated. It may be given in doses of  $\frac{1}{10}$  grain. It is claimed to produce no disturbance of digestion or of the nervous system. It is to be hoped that this drug will be subjected to very close investigation to confirm or disprove the claims which have been made for it, and establish its exact position in our materia medica.

#### HOPEINE.

THE manufacturers of hopeine appear to have themselves not clearly decided as to what the exact composition of hopeine ought to be. We have already called attention in these columns to the fact that hopeine seems principally to be morphine. This has been proved by the examination of a large number of independent observers. We have also referred to the fact that it has been found by Dr. Paul to contain cocaine, and Dr. Paschikis, in the *Pharmaceutische Post*, April 17, 1886, now believes that he has proved that hopeine is a mixture of a substance which is either morphine, or absolutely identical with it, and another base which is soluble in ether, and which is much more powerful than morphine, and which differs from it in its action on the organism. This latter substance, which responds to all the tests for alkaloids in its

physiological action and chemical tests, appears to be hyoscine.

#### AN IMPROVED ELECTRIC BATTERY.

WE have received from The Electro-Medical Battery Company, of Kalamazoo, Michigan, an example of their Improved American Pocket Battery. This is in its construction based upon the French Gaffé, or bisulphate of mercury battery, its chief difference being in a very great improvement of the cell, which is closed, instead of open, as in the original.

The great drawback with these batteries is that they cannot be made to yield slowly interrupted currents, but they are much cleaner, more portable, and more easily managed by the ignorant than are the acid batteries. The workmanship of the American battery, so far as inspection can go, is good. It has well stood what tests we have been able to give it, and certainly affords a powerful current.

#### Reports on Therapeutic Progress.

##### ANEURISM OF THE THORACIC AORTA TREATED BY GALVANO-PUNCTURE.

At the meeting of the Clinical Society of London, held May 14, 1886 (*Medical Press*, May 19, 1886), DR. CHURTON read notes of a case of thoracic aneurism treated by galvano-puncture.

A strongly-built man, æt. 45, had in 1880 an aneurism which protruded through the left chest-wall. He was then in the Leeds Infirmary, under the care of Dr. Clifford Allbutt, and was treated by iodide of potassium (afterwards continued for three years), and by galvano-puncture upon two occasions. After each puncture pulsation ceased for two or three days, but finally remained as before. The aneurism, however, did not increase in size until last year. In June, 1885, he was admitted under the care of Dr. Churton, a second tumor having appeared in front of the lower part of the sternum. This grew rapidly. With Dr. Allbutt's concurrence, Mr. Teale, who had operated upon the patient previously, applied the galvanic needles, fifteen cells of Leclanché's battery being used for twenty minutes. Blood-débris ran from the negative puncture. The pulsation ceased, but returned on the fourth day. The operation was repeated on October 2 with like result. He

began about this time to expectorate two or three drachms of blood-stained mucus daily. On October 27 galvano-puncture was used for the third time. The tumor was tympanitic for a few hours, but did not cease to pulsate. On November 9 it was so much increased in size and its walls were so thin that a fourth puncture was made, Dr. Griffith, the resident medical officer, operating in the absence of Mr. Teale. The current was passed for twenty minutes. Pulsation entirely ceased, and the patient seemed to have gained a respite, but suddenly died twenty minutes after the operation from rupture into a bronchus of the first aneurism, which had hitherto given no new sign except the very small quantity of bloody sputum. At the autopsy, an erosion, half an inch in diameter, almost blocked up by a clot described below, was found in the upper division of this sac. Except in the arch, the aorta was only moderately atheromatous. One testis had undergone fibrosis. The orifice of the first aneurism was about an inch in diameter; the wall of the sac was as firm as cartilage. The middle of the sac was occupied by a firm clot larger than a cricket ball; the lower part of the sac was lined by laminated clot, thin around the orifice, gradually becoming thicker above, and quite smooth. The upper aspect of the central clot was rough. A fissure between the wall and the clot connected the two chambers of the primary sac. It seemed that after the deposition of clot upon the entire sac, with closure of the upper part by formation of a very thick layer, the layer had been stripped from the roof of the sac by the blood which found a way through the fissure, and then enlarging this part of the sac formed a projection on the exterior of the chest. A constriction in the sac, marking the position of the large mass of clot, suggested this view. The growth of this sac was arrested by the firmness of its wall except at two points. An orifice a third of an inch in diameter existed at the lower part of the upper division, just outside the chest. This led to a second sac, the walls of which were soft, and its interior irregular, except where the sternum, quite uninjured, formed its limit. The front wall was composed merely of skin, and irregular bands or trabeculae of connective tissue of varying thickness, disposed like the carnae columnae of a right ventricle. This was the cavity in which the galvanic needles had been inserted. It contained no laminated clot; the surface was smooth and uninflamed. A soft jelly of pinkish color, too fragile to be preserved, and

some blood-débris were contained in the cavity. The cessation of pulsation had been due to entanglement of this clot in the short, narrow canal leading from the orifice into the cavity. The temporary cessation of pulsation noted in the large aneurism five years ago was probably due to a similar entanglement of soft clot in the narrow fissure above mentioned. The formation of such a clot and of blood-débris in the cavity of a perfectly open aneurism, one would suppose to be not free from danger.

#### ASEPTOL.

Orthoxyphenylsulphurous acid is the somewhat cumbrous name for a compound destined for popular use, and this fact may to some extent excuse the adoption of the more suggestive title of "aseptol" for an article that was to be put into the market as an antiseptic. Both these names are, however, now to be displaced in favor of "sozolic acid" (from *σωξω*, I preserve), M. SERRANT being anxious to avoid an erroneous inference from the termination in "ol" that the compound is of a phenol character, and to indicate that it has the properties of a definite and well-characterized acid (*Comptes Rendus*, May 10, p. 1079).

Sozolic acid, in fact, besides being soluble in water in all proportions, is described as combining perfectly with bases to form salts, and it is to its capability of saturating ammoniacal bases that its antiseptic action is attributed. The difference in chemical action between carbolic acid and sozolic acid is seen in the fact that red litmus-paper placed in a flask containing ammonia gas, after the introduction of sufficient carbolic acid to mask the odor of the ammonia, is turned blue, while, if sozolic acid be used, the red litmus does not change color. M. Serrant also points out that sozolic acid is an "ortho" compound, and that the antiseptic properties of compounds in the aromatic series, which includes the best antiseptics, seem to depend upon their capability of forming an anhydride that is only yielded by the "ortho" compounds; for instance, orthobenzoic acid, or salicylic acid, is antiseptic, while paraoxybenzoic acid is not. M. Serrant claims that sozolic acid exceeds salicylic acid in antiseptic power. This he accounts for by comparing the formula of sozolic acid ( $C_6H_4(OH.SO_2OH)$ ), which contains the sulphuryl radical, with that of salicylic acid ( $CHOH.COOH$ ), where its place is taken by the carbonyl radical. The superiority of sozolic acid over competing anti-

septics in other respects is also claimed, to an extent, indeed, that is rather unusual in a paper read before the Academy of Sciences. —*The Pharm. Journal and Trans.*, May 29, 1886.

*A NOVEL PROCEDURE FOR THE REMOVAL OF SUBGLOTTIC LARYNGEAL GROWTHS.*

At a recent meeting of the American Laryngological Association, DR. WILLIAM JARVIS read a description of a novel procedure for the removal of subglottic laryngeal growths (*Med. News*, June 12, 1886).

J. C., aged 35 years, consulted him on March 22, 1882, for the relief of a difficulty of speech and of breathing. The trouble with the voice was noticed two years before, the difficulty in speech appeared one year before coming under observation. The laryngoscope showed a mass of papillomatous tissue occupying the cavity of the larynx. The vocal cords and ventricular bands were not involved. An attempt was made to seize the growth during phonation, with the Mackenzie forceps, but only a few pieces were removed. The *écraseur* was then tried, but it was found impossible to use this instrument on account of the wire being seized by the spasmodic contraction of the vocal bands and displaced. Chromic acid applications were then tried, but although the growth was touched, it was found impossible to limit the application to the diseased structures. The patient then disappeared, and did not return for a year. His condition was then much worse, and the difficulty of breathing greatly increased.

Dr. Jarvis then determined to try the following plan, and, if this failed, to remove the growth through an opening in the windpipe. A forceps, similar to the Mackenzie instrument, but heavier, was secured. Through the tips of the blades holes were drilled, and through these was passed a piece of No. 00 piano-wire, which was conducted through a second opening at the angle of the blades and out to the handles, where it terminated in a loop, into which the extremity of the index-finger could be placed. When the blades were separated, this wire formed a cross-bar, uniting their extremities. When the blades were closed, the loop of wire could be drawn up by the finger. The operation was performed without an anæsthetic. The tongue was depressed, and, with the aid of the mirror, the forceps was introduced into the cavity of the larynx. The mirror was

then removed, and the forceps carried down to the glottis, through which the tip of the instrument was forced with considerable trouble, on account of the spasm. The instrument was carried into the trachea sufficiently far to be sure that it was below the attachment of the growth. The blades were then separated, and pressing against the anterior wall of the larynx, the instrument was gradually raised until the wire was caught. The blades were then closed and clamped, the loop of wire drawn in, and the forceps removed, bringing with it a growth. The laryngoscope showed a second growth, which was removed in the same way. Breathing was at once rendered easy, and the speech became natural. The patient said that the presence of the forceps, although uncomfortable, caused no pain. This is the only case on record of the removal of a subglottic tumor without anæsthesia and without an opening into the larynx.

*THE TREATMENT OF STRICTURE OF THE URETHRA BY ELECTROLYSIS.*

At a recent meeting of the Royal Medical and Chirurgical Society a paper on this subject was read by W. E. STEAVENSON, M.D., M.R.C.P., and W. BRUCE CLARKE, M.A., F.R.C.S. (*Brit. Med. Journ.*, May 29, 1886). The more extensive use made of electrolysis in surgery and gynecology abroad, and especially its successful employment in the treatment of stricture of the urethra, had induced the authors to undertake a series of observations to test the accuracy of the reports which had reached England. Their results bore out in every particular the results of success they had received from America. Electricity, on account of its power of splitting up compounds into their chemical elements, could be used as a substitute for ordinary caustics to the human body. It could be used with especial advantage to parts difficult of access, such as the male urethra and the uterine cervical canal, and it could also be applied to these and other regions where the application of other caustics was attended with a certain amount of danger. Its effects could be limited to the points touched by the electrode. The caustic effect could be arrested, or not commenced until the applicator, in the form of the electrode, was *in situ*; and the duration and extent of the caustic action were entirely under the control of the will of the operator. The treatment of stricture of the urethra by this method was the most simple, and, per-

haps, the most striking in its results, and had, therefore, been selected as the first on which to collect and report observations. In this paper, the details were given of six cases of stricture of the urethra treated by electrolysis, the *modus operandi* was explained, the steps of the operation were given, and the advantages of this method of procedure were summed up. There was usually no bleeding. If hemorrhage did occur, it was accidental, and usually showed that too strong a current had been used; no anæsthetic was required. If pain or discomfort were produced, it was trifling. The patient could, in the case of slight strictures, pursue his ordinary occupation during the period of treatment. No antiseptics were required, as the process itself was aseptic. In the majority of cases, there was no contraction or return of the stricture. Eschars produced by caustic alkalies were said to heal with less contraction than wounds produced in any other way, and electrolysis with the negative pole of a battery was a means of applying the same destructive action as was caused by the caustic alkalies to parts difficult of access in a way which was impossible by any other method. Probably, other chemical decompositions and combinations took place at the negative pole besides those characteristic of the caustic alkalies, but they had not, up to the present time, been thoroughly made out.

MR. BERKELEY HILL was much interested by the paper, but was sorry to say that he could not find the conclusions of the authors quite satisfactory. The cases had been related, after the manner of the American writers on the subject, without enough detail as to the size, nature, and position of the stricture. One case had suffered from stricture, more or less, for twenty years; he had often been relieved for a time by ordinary dilatation, and then had slowly relapsed. The relief given by Dr. Steavenson and Mr. Bruce Clarke dated only from about eight months ago, and he expected that his discomforts would return; at any rate, at present, there was no proof of a cure. It was universally admitted that, by patient pressure, a larger catheter could be passed; but he thought the authors had hardly made due allowance for this in their account of the increased size of the electrical bougies passed, which might perhaps be due to patience as much as electricity. He had himself carefully considered the American cases that Dr. Newman had published, and had followed his plan in treating one case of his own. There was stricture,

two inches and a half from the meatus, probably behind an old urethral abscess; he could see clearly with an endoscope, which he was sorry the authors had not used. He passed a needle, which formed one pole of the electric circuit, into the scar-tissue, and could see, with the endoscope, that nothing more happened than the occasional liberation of a bubble. The patient felt no pain at all, except on making and breaking the current; he measured the current's strength by the patient's feelings. After fifteen minutes' application of the current, he found the stricture enlarged from 19 to 20 of the French scale. After further treatment, in the same manner, it gradually contracted from 20 to 16; and as cure seemed very unlikely by such a process, he resorted to other methods, and found no difficulty in widening it.

MR. F. SWINFORD EDWARDS had treated a case, with the help of Dr. Steavenson. He had first seen the patient two and a half years ago, when he found three strictures, two penile and one subpubic, of size No. 12 (French); these he gradually dilated to No. 25. For two years the patient was lost sight of, and then returned with three strictures, distant  $\frac{3}{4}$  inch, 4 inches, and  $5\frac{1}{2}$  inches from the meatus, admitting only No. 4 (French). Dr. Steavenson applied a No. 3 electrode and current of from 5 to 8 milliamperes; this did not pass; but the flow of urine was improved, and, a few days later, a bougie, No. 10, could be passed; and, after a few weeks under electrical treatment, a bougie, No. 26 steel or No. 28 pewter, could be admitted. Whether it was to be called strictly a cure or not, it was certainly satisfactory in enabling the patient to get about and do his work; and his case was a bad one, which would otherwise have needed treatment with an Otis's dilating urethrotome. He hoped the treatment would be further investigated in hospital cases.

MR. G. BUCKSTON BROWNE thoroughly agreed that it would be a very good thing if the practised hands of the seniors in the profession could be brought to try this method; for there was hardly any point in which more experience was needed than in estimating and accurately diagnosing stricture. He was inclined himself to attribute the results embodied in the paper to the dilatation, not to the electricity; else why was it found advisable to use gradually larger and larger electrodes? Even pressure, without passage of a catheter, often did much to facilitate the passage of urine. He had considered Dr. Newman's cases with some care, and could

not help calling attention to one remarkable point in them, that they were, every one of them, successful.

DR. STEAVENSON observed that very little of the reply fell to his share. He was not familiar with the endoscope which Mr. Berkeley Hill had shown. In Mr. Hill's cases, he understood there had been puncture, and he certainly was not surprised that contraction had followed. They had used bougies, of gradually-increasing size, to keep in contact with the walls of the urethra.

MR. BRUCE CLARKE said he had been quite prepared to meet the two chief objections that had been urged : that the cases were not really of organic stricture ; and that they were not really cured. As to cure, he was bound to admit that the operations had been performed last August, and not treated since ; they were under observation, and had not relapsed ; only time could prove their ultimate cure. As to the point that they were spasmodic strictures, he could not admit it ; in one of the cases, there had been extravasation of urine ; at first, nothing could be introduced, but, after electrical treatment, he could pass No. 11 (English), and that was a success as great as any after a cutting operation.

The editors of the *British Medical Journal* for the same date comment on this mode of treatment as follows :

"The treatment of urethral stricture by electrolysis is one of which there is, as yet, very little practical knowledge in England ; and we confess we were very glad to see it so well brought forward as it was last Tuesday evening by Dr. W. E. Steavenson and Mr. Bruce Clarke, at the Royal Medical and Chirurgical Society. Interest in the subject was first aroused by one of the daring attempts of American surgery, made by Dr. R. Newman, of New York, who published, about eighteen months ago, 'Tabular Statistics of One Hundred Cases of Urethral Strictures treated by Electrolysis, without Relapse.' It would have appealed, perhaps, even more strongly to those who believe in the fallibility of human nature, if there had been one or two relapses. The fashion of operating admits of many small variations ; but the essential points are, that one pole of the battery shall be of metal, and in contact with the surface of the stricture, and the other widely spread out by means of a pad over a considerable surface of the body, the back, or elsewhere ; and that between these poles a current of considerable strength should be passed. It is found most successful and least uncomfortable that the

negative pole should be in contact with the urethra ; the positive, with the body. A current may be passed which is strong enough to act upon the stricture without giving any discomfort, except, perhaps, at the moments of making and breaking. What the exact action of the current upon the cicatricial tissue may be we are hardly in a position to say, though the actual watching of the process by means of an endoscope, as practised once by Mr. Berkeley Hill, may throw more light upon it. It is covered, at present, by the word 'electrolysis,' of which, when applied to fibrous tissues, we must admit that the limits are somewhat indistinct. At any rate, it is alleged that not only does the resistance of the stricture give way, but that more or less of the tissue which forms it is turned into a slimy mass of broken-down epithelium, and so disappears, without leaving a contracting cicatrix. The *a priori* impression is certainly strong that, where tissue has disappeared, there must be a cicatrix ; and that, if there is a cicatrix, it must contract, sooner or later. Those who have practised electrolysis will gain a much more attentive hearing and a more zealous following when they can show a longer maintenance of good results than the eight months which have elapsed since Mr. Bruce Clarke's operations. When the malady is chronic, it naturally needs a long time to judge of the cure ; but, at the same time, the habits of scars, due to different causes, are known to vary greatly in contraction, and it is possible enough that there may be less contraction after electrical action than any other, even than those from caustic alkalis. And, further, we are not yet experienced enough to assert how completely similar or dissimilar to an ordinary cicatrix this process of electrolysis may be. That it deserves trial from the older and most skilled hands there would seem to us little doubt ; and we can imagine it most convenient that the electrical necessities should be managed by the younger students of that somewhat difficult class of instruments."

#### SALOL.

"Salol" is the name of a new compound prepared by PROFESSOR NENCKY, which is said to possess powerful antipyretic and antiseptic properties, and to be capable of replacing advantageously sodium salicylate in cases where that salt is badly tolerated. Salol is a derivative of salicylic acid, in which one atom of hydrogen is replaced by the phenol group. It is described as a white powder,

having a faintly aromatic odor, and as it is almost insoluble in water, perfectly tasteless. Professor Nencky states that in the organism salol undergoes a simple splitting up into its two components, without any further modification, both being found in the urine. The decomposition appears to be affected by the pancreas, since the powder brought into contact with comminuted pancreas is at once decomposed. Assuming, therefore, that the decomposition first takes place in the duodenum and not in the stomach, Professor Nencky thus explains how it is that its administration is not followed by disagreeable after-effects. The dose is about the same as that of salicylate of sodium, but as much as 4 grammes (60 grains) may be given daily. The urine, after its administration, becomes very dark, almost black, as after the ingestion of carbolic acid, of which salol contains thirty-eight per cent. No toxic symptoms, however, are produced, probably because the phenol passes through the stomach in combination and is not absorbed. The antiseptic properties of salol are also said to render it useful in the treatment of putrid affections of the mucous membrane.—*Pharm. Journ. and Trans.*, May 29, 1886.

#### THE VALUE OF LANOLIN.

Lanolin appears to be more and more attracting the attention of physicians as a means of applying various substances in the form of ointments to the skin and insuring their absorption. That it is absorbed more readily than either lard or vaseline has been claimed for it, and this has been proved to be a fact by some experiments made under the supervision of Dr. H. W. Blanc at the Skin and Cancer Hospital, New York, and reported in the *Journal of Cutaneous and Venereal Diseases* (June, 1886) by DR. GEORGE HENRY FOX. The method employed in these experiments was to mark off on the anterior surface of the forearms of a young girl spaces four by six inches in extent. Upon the space so marked on the right forearm 15 grains of lard were rubbed for fifteen minutes. The left forearm was treated with lanolin in the same manner. The lard was softened more quickly by the heat of the skin and hair, and was spread much more rapidly over the surface.

With as nearly an equal amount of pressure as it was possible to give, the lanolin was found to redden the skin more readily than the lard. At the expiration of the fifteen minutes, the greasy matter remaining upon forearm was carefully collected by means

of a spatula and weighed, with the following result :

Weight of lanolin used.....	15 grains.
“ “ “ removed from skin.....	5 “
“ “ “ absorbed.....	10 “
Weight of lard used.....	15 grains.
“ “ “ removed from skin.....	10 “
“ “ “ absorbed.....	5 “

We see, therefore, that while two-thirds of the lanolin disappeared during the rubbing, only one-third of the lard was lost.

To test the comparative rapidity of absorption of lard and vaseline, similar spaces were marked off upon the back of a young man upon either side of the spine and beneath the scapulæ. Fifteen grains of each were rubbed in for fifteen minutes, and the amount scraped off was weighed as before, and with the following result :

Weight of lard used.....	15 grains.
“ “ “ removed from skin.....	8½ “
“ “ “ absorbed.....	6½ “
Weight of vaseline used.....	15 grains.
“ “ “ removed from skin.....	9½ “
“ “ “ absorbed.....	5½ “

We note in this experiment that the lard was more readily absorbed than the vaseline, although the difference was not as marked as in the case in which the lard and lanolin were tested.

As a proof of the rapid absorption of drugs by means of lanolin frictions, Liebreich states that a solution of bichloride of mercury in lanolin, of a strength of 1 to 1000, will produce a metallic taste in the mouth, after being rubbed into the skin. Dr. Fox has rubbed repeatedly upon his own skin, as well as upon others, a lanolin ointment of ten times this strength, and failed to get any gustatory proof of its absorption. In some subjects of his experimentation, however, the peculiar metallic taste in the mouth has been noted, but it is possible that a similar effect might have followed the use of lard or even vaseline. As an improvement in our present method of endermic medication, particularly in the inunction cure of syphilis, lanolin may prove to be of great value, but time will be required to settle this point.

Without discussing further the theoretical use of lanolin, let us consider the question as to its practical value when tested in the treatment of skin-diseases. Since the first importa-

tion of lanolin from Germany, Dr. Fox states that he has been using it in nearly all cases in which he had occasion to prescribe an ointment, and he failed to see any remarkably beneficial effects from its use. On the contrary, it has proved objectionable in some instances on account of its color and consistence, and, in certain cases of acute inflammatory disease of the skin, it has not been found to be as bland as one has been led to expect. When he used a lanolin ointment upon one side of the body, and a lard or vaseline ointment upon the opposite side, the patient has usually expressed a preference for the latter, and in no case has the rapid absorption of the former been so marked as to attract notice.

In conclusion, his views respecting lanolin may be summed up in the following statements:

1. Lanolin is more readily absorbed by the skin than any other fatty substance.
2. As a basis for ointments, it is useful when an effect upon the deeper skin or upon the whole system is desired.
3. On account of its firm consistency, it is advisable to mix with it a certain amount of lard, especially in cold weather.
4. When applied to a highly-inflamed skin, lanolin may not prove as bland as *fresh* lard or *pure* vaseline.
5. Considering its recent introduction, its questionable superiority, and its present cost, it cannot be recommended as yet as the best basis for all ointments.

#### THE TREATMENT OF ERYSIPELAS WITH CREASOTE.

DR. H. J. FOX, writing in the *St. Louis Medical Journ.*, May, 1886, claims that creasote may be regarded almost as a specific in the treatment of erysipelas. His manner of application is to keep the parts constantly covered with cloths wet with a solution of 6 to 20 drops to the ounce of water. In ulcers or wounds it may be used in the form of a poultice by stirring ground elm into the solution. The strength to be regulated according to the virulence of the attack. Ordinarily, 10 drops to the ounce is strong enough for the cutaneous form of the disease, and in dressings for wounds or recent injuries. If the inflammation threatens to spread rapidly, it should be increased to 20 or more drops to the ounce of water.

The antiseptic properties of this remedy render it of additional value, as it will certainly

destroy the tendency to unhealthy suppuration, and thus prevent septicæmia.

In the treatment of hundreds of cases of erysipelas, according to Dr. Fox, but a single fatal case has occurred, and that one in an old and depraved system. In the less violent attacks no other remedy was used, but where constitutional treatment was indicated, the usual appropriate tonics were prescribed.

#### PARALDEHYDE AS AN ANTIDOTE TO STRYCHNINE.

The property of paraldehyde of greatly reducing the activity of the spinal cord as a reflex centre, led PROF. BOKAI (*Pharm. Post*, April 24, 1886) to test paraldehyde as an antidote to strychnine-poisoning. The results of his experiments made on rabbits, cats, and dogs were almost invariably favorable. The animals first received a non-fatal dose of paraldehyde, and then an absolutely lethal dose of strychnine was given. In no case did the strychnine produce death. If, however, doses of paraldehyde, which are themselves fatal, were given to animals, the largest doses of strychnine were not able to remove the poisonous symptoms of the paraldehyde or to delay the fatal processes. It would appear, therefore, that the antagonism between these two drugs is only one-sided. Since the hypnotic action of paraldehyde is much more rapidly produced than the poisonous symptoms of strychnine, the hope is not unreasonable that paraldehyde, if given soon after the ingestion of a poisonous dose of strychnine, might serve to antagonize it. Prof. Bokai, strange as it may seem, does not appear to have made any experiments in this connection. Should paraldehyde be proved to be an antagonist of strychnine, its use for this purpose is almost without risk, since, it is free from the unfavorable action on the heart possessed by chloroform and chloral, which also have some antagonistic power to strychnine.

#### A NEW METHOD OF MEASURING THE TEMPERATURE IN CHILDREN.

All physicians know how difficult it is in certain cases to take the axillary or rectal temperature in children. One of the principal difficulties is in the restlessness of the child, which prevents it from keeping quiet long enough to obtain a record of the temperature. DR. FILATOFF (*Revue Mensuelle des Malad. l'Enfants*, May, 1886) proposes a

method which, while it is true fails in giving an absolutely exact temperature, serves, at least, to give an estimate which is sufficient in the majority of cases. This method consists simply in observing not the ascent of the column of mercury, but, on the contrary, its fall. He first causes the mercurial column to rise considerably above the estimated temperature by rubbing the bulb with the hand, or in any way warming it. When the temperature reaches 107° F. he rapidly passes the instrument into the axillary space, previously laid bare, and notes the distance which the column falls in one or two minutes. He thus obtains a temperature which almost exactly approaches the true temperature of the patient.

#### CLIMACTERIC DIABETES.

MR. LAWSON TAIT calls attention in the *Practitioner* (June, 1886) to the fact that in a large majority of cases of eczema of the vulva at the climacteric period the disease will be due to the presence of sugar in the urine. He states that he has not yet come across a case of this kind in which he has failed to find sugar. The disease seems to begin at or near the arrest of the menstrual function, and to extend over a period of several years, then terminating in all probability by nature's own process. The sufferings of the patient are, according to Mr. Tait, much diminished and the duration of the disease probably shortened by the free administration of opium. The eczema and pruritus are to be relieved by ointments containing such substances as will arrest fermentation in sugar. Of these, he believes that the old-fashioned hepar sulphuris is the best. He also has used a lotion of hyposulphite of sodium 1 oz. to a quart of water with immense advantage, but it is only by frequent ablutions and syringing that comfort can be so obtained. Opium he uses in 1 gr. dose three times a day and 3 grs. at bedtime; this quantity may be gradually diminished as the patient improves. The chronic vaginitis, which will frequently be found to complicate such cases, may be cured by swabbing out the vagina two or three times with strong carbolic acid, together with an application of oleate of zinc.

#### NERVE-STRETCHING FOR LEPROSY.

At a recent meeting of the Harveian Society, DR. E. DOWNES read a paper on Nerve-stretching for Leprosy, founded on a large ex-

perience in nerve-stretching for leprosy and sciatica in Kashmir (*Lancet*, June 5, 1886). Of forty-two cases recorded, thirty-two were well-marked cases of leprosy, and in all these anæsthesia of the lower extremities was an early and well-marked symptom. It was sometimes absolute and sometimes partial, being occasionally accompanied by absence of pigment or by tubercles, the latter occurring more commonly on the face, and often with severe neuralgia of the deeper parts. Ulceration commonly occurred in course of time, and especially in the feet, possibly beginning in some cases as a result of direct injury to the anæsthetic tissues, and often extending to complete destruction of the parts. Some of the cases recorded had lasted from one to seven years, and longer in two instances. The operation was done through a three-inch incision at the back of the thigh, the finger being hooked round the nerve, and the limb lifted from the table. All the cases were benefited by the operation, and in some the ulcers healed completely, and sensation was nearly restored to its normal state; the latter generally took place in the first few days. This success was fully appreciated by the patients, who repeatedly sent their friends suffering from leprosy to be similarly operated upon. The author observed that an exclusive diet of dried fish was not always an element in the production of the disease, many of his cases coming from districts where none was obtainable. He believed the ulceration to be due to peripheral neuritis, consequent upon some altered condition of the blood, for which the presence of bacilli might be answerable.

DR. BUZZARD observed that these cases afforded direct proof of the relation of leprosy to affections of the peripheral nerves, and not to those of the spinal cord. The neuralgia and the immediate results of stretching were strong evidence in this direction. Although few English medical men had to deal with leprosy, he thought that a practical knowledge of the disease would lead to more thorough investigation of other forms of degeneration of nervous origin. Leprosy was at one time endemic in England, and he suggested that remnants and traces of it might still be existent in the form of localized atrophy or leukoderma.

DR. DOWNES, in reply to questions, stated that in one of his cases sensation had continued good for two years; none others had been under observation for so long a period. He had obtained uniformly good results in nerve-stretching for neuralgia and sciatica.

*SUCCESSFUL EXTIRPATION OF THE  
SPLEEN.*

*La Gazzetta degli Ospitali* (May 23) reports a case from the surgical clinique of the University of Genoa in which PROFESSOR A. CECI removed a greatly enlarged spleen. The patient, an imperfectly developed and very thin girl, aged 17, weighing 40 kilogrammes, and 1.40 metre in height, with very small pulse, had had an abdominal tumor from birth. The transverse diameter of the tumor was 34 centim., the vertical 23 centim., and the circumference about 64 centim. The anterior surface was smooth and convex, the margins sharp and fissured. The posterior surface presented a large lobe on the left. The abdominal walls were very flaccid, so that the tumor could be completely rotated vertically and transversely, and also be pushed into the left hypochondrium, whence, however, the respiratory movements soon caused it to advance to the front of the abdomen. The liver was in normal position. The enormous size of the floating spleen interfered with the patient's movement and nutrition, and was an occasional source of very severe attacks of pain, radiating from the left hypochondrium to the præcordial region and the left upper limb, and attended with violent dyspnoea and insensibility. Extirpation having been resolved upon, it was performed on March 20, with strict antiseptic precautions. The incision in the linea alba from above downwards through the umbilicus was 23 centim. ( $9\frac{1}{4}$  inches) in length. On opening the abdomen, serious signs of suffocation compelled the suspension of the operation for nearly thirty minutes. Anæsthesia having been commenced with bichloride of methylene, chloroform was substituted for it. A triple catgut and carbolized silk ligature having been applied to the pedicle, it was dropped in. The peritoneum was sutured separately. The abdominal walls were brought together by three metallic points, after Billroth's method. The splenic artery was larger than the subclavian. The whole operation, including the interruption, lasted an hour and a quarter. Violent delirium and nervous phenomena simulating angina pectoris soon followed. For two days the pulse could not be counted, and the respiration varied from 70 to 80 per minute. The treatment was by oxygen and nutritive clysters. The wound was first dressed on the eighth day, and almost the whole of the wound-tract suppurated. In spite of strict antiseptic treatment erysipelas supervened, and yet the patient recovered. On

April 22 (thirty-one days after the operation) her condition was reported as excellent, only a small superficial wound remaining. The extirpated spleen, with the contained blood, weighed 2400 grammes, equal to 37,036.8 grains, or 77.16 ounces. A courteous note just received from Professor Ceci states the patient is in good health; pulse 80; respiration 22; weight increasing rapidly; complexion florid.—*Lancet*, June 5, 1886.

*ON THE TREATMENT OF NÆVUS BY  
EXCISION: CLINICAL ANALYSIS  
OF 564 CASES OF NÆVUS.*

At a recent meeting of the Clinical Society of London, MR. R. W. PARKER (*Brit. Med. Journ.*, June 5, 1886) read notes of a case of suppurating nævus situated on the back of a child, aged 10 months. It was of the mixed variety,—that is, partly cutaneous and partly subcutaneous. When first seen, it measured  $2\frac{1}{2}$  by  $2\frac{1}{4}$  inches, and was considerably raised above the surface. The central (cutaneous) portion was bright red in color; the subcutaneous (raised) portion extended several inches around this central portion. It was stated that it had rapidly increased in size within the last few weeks. The nævus was excised through an elliptical incision, the edges of which were subsequently brought together with catgut sutures, and then coated with iodoform collodion. The child made a rapid recovery, and left the hospital within three weeks. After removal, the nævus was cut into, and found to contain about one ounce of blood-stained pus. The interior of the sac was rough and corrugated, and divided into numerous loculi by strands of shreddy tissue running across the cavity. This case was selected as being unusual on account of the suppuration within the sac; and because, on account of the size and of the largely subcutaneous nature of the nævus, it well illustrated the adaptability of excision as a means of treatment for this (mixed) variety of nævus. Mr. Parker divided nævi into three chief classes,—the cutaneous, the subcutaneous, and the mixed variety, the last-mentioned being by far the most numerous. For cutaneous nævi, one of the simplest and most efficacious methods of treatment was the application of fuming nitric acid; for the subcutaneous variety, he advocated electrolysis or excision; for the mixed variety, excision was regarded as the surest and most speedy, as well as the most radical method. The paper

concluded with an analysis of 564 cases, and a description of the histological characters of nævus, microscopic specimens of which were exhibited.

MR. GOLDING-BIRD had found good results from the "barbarous practice" of ligation. He took exception to the sweeping statement that excision should be applied to all cases. Treatment must depend on the situation and characteristics of the tumor. Ligation was much preferable in cases which occurred in out-patient practice. A less scar ensued after ligation than after excision, and this latter method was inapplicable to nævi of the scalp. In nævi below the lower eyelid, and at the end of the nose, the galvanic cautery alone could be employed, and neither ligation nor excision could be, in this situation, adopted. Properly employed, the cautery left a minimum of scar, and the least amount of contraction. The vascular tissue was gradually supplanted by cicatricial tissue, the contraction of which cured the rest of the vascular tissue. In all such treatment, the cautery should invariably be applied circumferentially at first; then this outer part, cicatrizing, nearly strangulated the central portion, which might be easily dealt with, at another sitting, by cautery, ligation or excision. Mr. Golding-Bird had lately employed this practice very often.

DR. WARD COUSINS asked if it was not possible that the specimen exhibited by Mr. Parker was undergoing spontaneous cure. The knife was the best treatment in some cases, but in others the worst. Some nævi disappeared under any treatment whatever. Nævi affecting the lids and nose, etc., ought to be very slowly treated; he himself treated them piecemeal, by frequent and long-continued scarification, by a double-edged cataract-knife. He approved of the large use of the actual cautery, as for small nævi of the face, and now never employed nitric acid, and never used the ligation under any circumstances whatever.

MR. PARKER had formerly much experience in the use of the actual cautery. For nævi about the nose and eyelid, he employed electrolytic needles, passed from the interior of the mouth or nostrils, where practicable, so as to avoid scars. He advocated excision, as being a radical cure, and because the after-treatment was simple, especially when the edges could be brought well together; any ordinary mother could, after three or four days, attend to the dressing of the wound. The child whose case he had related had

probably had some injury to the nævus, in consequence of which it was suppurating.

#### CALOMEL AS A DIURETIC.

JENDRAFSIK, of Buda-Pest, noticed the diuretic action of calomel in a patient suffering from dropsy, who, for other reasons, was under mercurial treatment by friction, and by the internal administration of calomel in small doses. The treatment with calomel lasted for several days, when an abundant diuresis set in, and the dropsy disappeared. Since then Dr. Jendrafsik has repeated his experience in a large number of cases, always with success (*Gaz. Méd. de Paris*, May 29, 1886). Calomel was administered in doses of 2 decigrammes (3 grs.) three or four times in the twenty-four hours. Larger doses caused diarrhoea, while gargles of potassium chloride served to prevent salivation. The diuretic action appears on the second day with such intensity that the patients are scarcely able to retain their urine; the polyuria may last from five to fourteen days. He thinks that the calomel acts by an osmotic action, the liquid transuded from the vessels being absorbed by the production of an inverse current.

#### MANACA IN RHEUMATISM.

DR. J. BERGER (*St. Louis Med. Journ.*, May, 1886) adds his testimony to the evidence which is being rapidly accumulated as to the value of manaca in rheumatism. He writes that he commenced the use of manaca in rheumatism about five years ago, and claims that it has given better results than any other single remedy than he has ever employed, and is perhaps better than any combination of remedies. He has used it in all forms of chronic rheumatism with good results, and he has employed it so often in such cases that he has no doubt as to its possessing anti-rheumatic properties to a great degree. He believes that it acts by eliminating lactic and uric acids from the system and, by assisting digestion and assimilation, prevents their reforming in excess. He reports three cases in which its use proved of service.

#### THE FREQUENCY OF DISEASE OF THE UTERINE APPENDAGES.

From a paper on the above subject published in the *American Journal of Obstetrics* for June, 1886, DR. HENRY C. COE draws the following conclusions:

1. Ovarian disease is *not* as common as it has been represented, the surgeons and *not* the pathologists being responsible for the prevalence of the contrary opinion.

2. Because an ovary is partially diseased it does not follow either that its functions have been materially impaired or that its removal is imperative.

3. The expressions "cirrhosis" and "cystic degeneration," commonly applied to the ovary, are mischievous terms, which are too often used in justification of *unjustifiable* operations.

4. Actual disease of the tubes is far less frequent than is generally believed. Lesser degrees of inflammation, especially slight "catarrhal salpingitis," are seldom appreciable to the pathologist, still less to the surgeon.

5. Many of the symptoms ascribed to disease of the uterine appendages are really due to *localized peritonitis*, and will *not* be removed by a removal of the appendages.

6. The physiology of the ovaries and tubes is still imperfectly understood; their pathology must then remain *sub judice*, and operations for their removal, on the ground of limited disease alone, must be regarded as largely empirical. To which he adds the prediction:

7. The present enthusiasm in this country in favor of Tait's operation will not endure, because it will eventually be discovered that the number of *permanent* cures is entirely out of proportion to the number of operations.

#### THE TREATMENT OF CONSTIPATION BY MASSAGE.

In the introductory lecture to the course of Pharmacology and Therapeutics delivered at the Westminster Hospital Medical School, DR. MURRELL referred at some length to the good results recently obtained in the treatment of habitual constipation by means of massage. The method he employs is a modification of that originally introduced by Mezger and Von Mosengal. *Pétrissage* of the abdomen is of essential value, the manipulations being performed in the direction of the ascending transverse and descending colon. It is usually associated with various forms of *tapotement*, for the production of which the open hand, the partly-closed hand, or its radial or ulnar border, may be employed. Vibratory movements are resorted to in obstinate cases, and it was stated that the action was usually remarkably prompt and certain. The best results were obtained

in cases of constipation associated with obesity, especially when the patient was unable to take much exercise. It probably acts in three ways,—(1) by increasing the intestinal and other secretions; (2) by stimulating the peristaltic action of the intestines; and (3) mechanically, by pressing the accumulated feces towards the rectum. The treatment is well known on the continent, and will, doubtless, in time be generally recognized in this country.—*Medical Press*, May 19, 1886.

#### SUGAR AND CORROSIVE SUBLIMATE AS A FIRST DRESSING IN WAR.

DR. HEIDENREICH, in a paper published in the *Vratch* (Nos. 19 and 20), strongly recommends as a first dressing on the field of battle a mixture of corrosive sublimate with powdered sugar, in the proportion of 1 to 1000. It is important that when this is prepared the sublimate should be evenly distributed, and this is easily effected by first dissolving the mercurial salt in a little spirit, and then carefully rubbing up the sugar with it. The spirit ultimately evaporates, and leaves a powdered mass of uniform composition. A little packet is supplied to each soldier, containing a capsule, in which is 5 grammes of the mixed powder,—*i.e.*,  $\frac{1}{100}$  of a gramme of sublimate,—for the purpose of sprinkling on the wound; also a good-sized piece of gauze impregnated with one-third per cent. of its own weight of sublimate by means of Bergmann's process, which consists of dipping it in a solution containing 10 parts sublimate to 500 glycerin, 1000 alcohol, and 1500 water. Some hygroscopic wadding is also supplied, and this, when inclosed between two folds of the gauze, forms a dressing measuring 650 sq. centim., which is large enough to cover a somewhat extensive wound. The whole is inclosed by means of a layer of varnished paper and a triangular bandage, which is fastened with two safety-pins. The author claims for this mixture of sugar and sublimate the advantage of being a particularly powerful antiseptic, and quite innocuous. Sugar, he says, is the best substance for diluting the sublimate, being itself somewhat antiseptic. This dressing has also the additional advantage of being suitable for use wherever water may be procurable. This, of course, is not always the case, and, where it is the source, is frequently in a marsh or pool of anything but hygienic appearance. Under these circumstances he advises that filtration should be resorted to, and consequently proposes that a kind of filter, consisting of flannel

nel impregnated with sublimate, should be included in the packets supplied to the men. The whole contents of the packet weigh only seventy-five grammes, and are exceedingly portable and inexpensive.—*Lancet*, June 12, 1886.

#### DIAGNOSIS OF GONORRHOEA IN THE FEMALE.

If there is any clinical truth in the statement put forward at a meeting of the Paris Obstetrical and Gynæcological Society by DR. MARTINEAU, a most important means of forming a true diagnosis is in the hands of medical men, and one which will save them much worry and anxiety. Many cases arise in which it is of the utmost importance a correct decision should be arrived at. It is claimed that in the case of gonorrhœal discharge the latter is always acid, while in the simple form of vaginal discharge it is alkaline. The reaction upon litmus-paper in this case settles the question. This would also form a very valuable means of deciding in cases of rape in which the persons committing the crime were supposed to have been suffering from gonorrhœa at the time, and to have imparted the specific disease to the victim. Further evidence may be looked for to establish or negative what, if true, will be a great step in advance in our clinical knowledge of the subject.—*Medical Press*, June 2, 1886.

#### THE USE OF LEMONS IN THE TREATMENT OF INTERMITTENT FEVER.

According to the Paris correspondent of the *American Practitioner and News* (June 12, 1886), DR. MASLENNIKOFF has treated twenty cases of intermittent fever with a decoction of lemons. Seven of the patients were affected by the fever for the first time, three for the second, the rest having passed previously through several malarial attacks. In thirteen of twenty cases a quotidian, and in seven a tertian variety was present. In sixteen cases the spleen was found to be enlarged and painful; in fourteen, both during the paroxysms and the intervals.

The decoction was prepared after Maglieri's method,—that is, every evening a whole fresh lemon was cut into very thin slices, put into eighteen ounces of distilled water in an earthen pot, and boiled (for two hours) until six ounces of decoction remained. On the next morning the liquid was forcibly strained through a piece of gauze, and then given to the patient to take

immediately in several gulps. The decoction was used in that way for ten or fourteen successive days. In none of the patients did any gastric disturbances occur.

The results obtained by Dr. Maslennikoff were not so successful as those by Dr. Putakhin and others. In only six cases, four of which were of quotidian fever and two of tertian, a cessation of the paroxysms ensued. For two of the remaining patients the paroxysms became less severe, and in three the type of fever underwent a change. In none did any alterations in size of the spleen take place. All cases where decoction of lemons had failed were subsequently mostly very rapidly cured by quinine. The general conclusion reached by the author is that, as far as severe Caucasian fevers are concerned, decoction of lemons has, except its agreeable taste and harmlessness, no advantages whatever over other substitutes for quinine.

#### THE TREATMENT OF PUERPERAL CONVULSIONS WITH PILOCARPINE.

We have two or three times in previous issues alluded to the use of pilocarpine in puerperal eclampsia. DR. JAS. MURPHY, in the *Lancet* for May 29, 1886, publishes notes of three cases of convulsion occurring in the puerperal state, in all of which pilocarpine seemed to reduce the severity and frequency of the convulsions, and all of the cases recovered, a fact which by itself is sufficient to indicate that in all probability the recovery was partly, if not largely, to be attributed to the use of this remedy. The alkaloid was given in the dose of one-third of a grain injected hypodermically, as often as every six hours or more frequently, if necessary.

#### URETHAN AS A HYPNOTIC FOR THE INSANE.

Urethan as a hypnotic in mental affections has been subjected to trial by Drs. OTTO and KOENIG in the Hospital for Lunatics and Epileptics in Dalldorf, who have published their results in the *Centralb. für Nervenheilkunde*. It was used in various cases of excitement, all of which are said to have been of a violent nature, in epileptics and hysterical patients, and in the stages of excitement which so frequently occur in idiotic children. In 23 cases 250 doses of this drug were given in watery solution; as much as from 30 to 60 grains or even 120 being given with

producing disagreeable results. In 10 cases of epilepsy, with depression and anxiety, its action was favorable. The authors' most favorable results were, however, obtained in the case of idiotic children, where 20 to 40 grains produced a very satisfactory result, without any disagreeable after-effects. In some of the cases, after the administration of the large doses, nausea was complained of; vomiting occasionally occurring, the patients objected to continuing the treatment with this drug, although the taste itself was not disagreeable to them.

In comparing its effects with chloral and paraldehyde, urethan did not appear to advantage, since the nausea and vomiting were more marked after urethan than after even paraldehyde, and the narcotic effects did not appear to be as marked. In cases of violent excitement, urethan, even in doses of 120 grains, produced no appreciable relief, and the authors think that its employment is best suited to cases of slight depression and anxiety, as seen in their epileptic cases. The above results were obtained in the treatment of the female wards of the hospital, and somewhat similar results were obtained in the treatment of male cases. Here also digestive disturbances, such as loss of appetite, nausea, and vomiting occurred, and here urethan was found to be of very little value in the treatment of violent cases of excitement, but it occasionally produced very satisfactory results in milder cases. The authors think that it is not as well borne or as valuable in its action as paraldehyde.

DR. ROTTENBILLER, writing in the same journal, relates his experience with urethan in the insane asylum at Budapest. Dr. Rottenbiller employed this drug, commencing with small doses,—that is, about  $7\frac{1}{2}$  grains, with which he obtained in almost all cases from one to two hours' sleep. From doses of 30 to 60 grains he obtained nearly always from six to eight hours of quiet sleep, though, when the excitement was marked, this hypnotic effect was less evident.

In most cases sleep occurred from fifteen to thirty minutes after the administration of the drug, though sometimes the patients remained perfectly quiet for two or three hours, and only slept for a short time. In only two cases did he find that it produced vomiting. His experience, therefore, leads him to feel confident that in most cases the administration of from 30 to 60 grains will produce several hours' quiet sleep without disagreeable after-effects, while larger doses are to be avoided.

From the fact that several hours' sleep could only be obtained with such large doses, and that the quantity necessary to produce this effect nearly always caused disturbances of the stomach, Dr. Rottenbiller made a number of experiments with the subcutaneous employment of urethan, using a thirty per cent. watery solution, and giving doses of about 4 grains. In nine cases in which he employed it in this way he found that only two injections of 4 grains produced six to eight hours' sleep, one-fourth the quantity being thus necessary to produce the effect obtainable when administered by the mouth. The injections caused no local reaction or abscess, and the patients did not complain of pain. Should these conclusions be confirmed, economy alone should recommend this mode of employment of the drug.

#### *SOME POINTS IN THE TREATMENT OF MORBUS COXÆ.*

At a meeting of the Academy of Medicine in Ireland, held Friday, March 19, PROF. THORNLEY STOKER read a paper advocating the employment of bone-drainage by trephining the trochanter as a treatment in cases of morbus coxæ of the femoral variety (*Medical Press*, June 9, 1886). He referred to the paper on this line of treatment read by Dr. Kirkpatrick before the British Medical Association in 1867, and to the later communication of Mr. Greig Smith in 1881. Prof. Stoker dissented from the use of caustic potash as recommended by Dr. Kirkpatrick, and advocated the use of a small trephine, supplemented by a drill if necessary. He gave details of two cases in which he had operated. In one, a well-marked case of femoral hip-disease in a girl aged 11, which had advanced to the second stage, a complete and rapid recovery had taken place. The other, a more advanced case in a child aged 5 years, had been much benefited, but was still under treatment. Prof. Stoker concluded his communication by putting forward these conclusions: 1st. That tunnelling the trochanter and neck is a reasonable and good practice in cases of femoral coxalgia, and is calculated to afford drainage and remove the products of disease; 2d. That it is more in accord with surgical science, while adopting the essential principles of Dr. Kirkpatrick's plan, to avoid the employment of caustic and rely upon the more precise use of instruments; 3d. That the extended application of the plan, so as to remove the diseased bone or even to drain a joint containing pus, as proposed by Mr.

Greig Smith, is a surgical proceeding worthy of every examination.

The CHAIRMAN said that the method which Mr. Stokes and Mr. Stoker advocated seemed to be very effectual for removing diseases of the hip-joint. That it originated with Dr. Kirkpatrick, of Dublin, was creditable to Irish surgery. He used it more for caries of the bone than for disease of the joint. Mr. O'Byrne had treated such cases in the early stage with hydrargyrum cum creta, which was now recognized as an antiseptic. Beyond that stage the operation for drainage offered a fair chance.

MR. CROLY recalled a paper which he heard read by Dr. Kirkpatrick on the treatment of joints by caustic, and said he saw some interesting cases thus treated by him in the North Dublin Union Workhouse Hospital, while for many years since he had himself been in the habit of using potassa caustica for disease of the metacarpal bones and of the small bones of the foot, as the scapoid, the cuboid, and cuneiform, with very successful results. In disease recurring after excision of the elbow he saw extraordinary results from boring with potassa caustica. On Tuesday, 16th instant, in the City of Dublin Hospital, he bored the trochanter in a child for all the symptoms of morbus coxæ, cutting down on the trochanter and boring with potassa caustica, making a funnel-shaped opening. That morning the child said she was free from pain. His experience led him to conclude that the caustic potash had more influence in relieving pain and tension than the use either of the knife or the trephine. Although he had failed to see the pus, he had not failed to cure the patient. There was no case he disliked so much as that of a child lying a year in bed, with weight and pulley and water-cushions, receiving good diet and cod-liver oil, and yet at the end the child might get up no better; but with the boring process the result promised to be different, and surgeons would not dislike meeting a case of morbus coxæ at the proper stage, cutting down on the trochanter and trephining or boring, or doing both, as being a very simple procedure.

MR. KENDAL FRANKS thought the operation ought to prove most successful on theoretical grounds, but not those on which the authors of the papers (who, however, deserved gratitude for reviving an operation originating in this country) relied. Undoubtedly opening into the trochanter and neck of the bone, with free drainage, promised good results. To talk of ascites as simple and strumous, and of the

disease beginning in the bones and synovial membrane, was the pathology of the past. The pathology of the present established two classes of cases,—those that were tubercular and those that were not. In the large majority of hip-joint cases the disease was localized tuberculosis, the same as in the lungs and the so-called strumous glands. Ollier, of Lyons, had microscopically proved that in strumous disease of the ankle and hip-joints it was tubercular disease of the bones and the synovial membrane and of the tissues round the joint. Statistics showed that of two hundred and fifty cases tabulated by Volkmann in his own experience, and in which microscopical examination was made of bone taken out at the time of operation, there were only five or six in which he could not find the bacillus of tubercle. Therefore they had to deal with the simple inflammatory condition of the joint and with the form much more serious which had its origin in tubercle. The simple variety was amenable to cure by counter-irritation and free drainage of the bone. In some cases of tubercular disease, also, Dr. Kirkpatrick's method promised good results. And why? Suppose the foci of the tubercle to be in the great trochanter or in the neck, what better treatment could there be than boring down upon it and scraping it out, and applying caustic potash or any powerful escharotic to destroy the foci and render recovery probable? Of course if the condition of the synovial membrane was simply one of inflammation, and the tubercular disease had not spread, they might expect the inflammatory condition inside the joint would subside when the irritation of the tubercular foci had been removed from inside the bone. But what good could ensue when the bacilli were found swarming over the synovial membrane was not so certain. If they could be certain that the case was a simple one, the simple modes of treatment were the best; but when the case was strumous,—*i.e.*, tubercular,—the only rational method was to remove the foci, and that could be done, if the disease began in the bone, by the boring and scraping process and the application of caustics. If the disease was in the synovial membrane he would scrape out the parts and apply, if necessary, a cautery; but in leaving germs behind there was danger, not so much of the return of the disease in the parts themselves as of the germs being carried along in the lymphatics and causing general tuberculosis.

Dr. Foy called attention to a modification of Sir Philip Crampton's treatment as practised

by Dr. Hardy, of Manchester, by slitting the capsule and cutting down on the periosteum.

DR. TATE mentioned that thirteen years ago a girl, aged 18, was operated on by Dr. Kirkpatrick at the North Dublin Union Workhouse Infirmary. The tubercular affection left her afterwards, and she was now in good health. She had had a child since the operation, and would soon have a second.

MR. STOKES replied. First, Mr. Stoker's objection to the use of caustic as part of the treatment had been answered by Mr. Croly, who pointed out its twofold advantage,—(1) in leaving a large funnel-shaped opening which facilitated drainage, and (2) in keeping the part open much better than if a simple incision were made. Thus, too, the danger was obviated of the wound being filled too rapidly by granulation, or of the external opening closing and leaving a cavity in which the fluids accumulated and suppuration ensued. The excellent results from that mode of treatment formed an argument against the very recent pathological views of Ollier and Volkmann, which they had been taken to task for not having adverted to, as to those cases being constantly so strumous in their character. He had heard Ollier's paper at the Congress in Copenhagen, and the impression produced was that Ollier was looking at all diseases of bones through tuberculous glasses, for every disease appeared in his point of view to be essentially tuberculous. With that view he could not agree, notwithstanding the high authority in support of it. The rapidity of cure from simple modes of treatment, and the absence of evidence of tuberculous disease in other parts of the body, pointed to the fact that those cases were by no means so frequently tuberculous as they were generally supposed to be. From his own experience certainly he did not think the majority of them were. As to the operation of opening into the large joints and scraping out the diseased parts, he had not done it in the hip-joint, but he had in others with very disappointing results, especially from that procedure in the knee-joint. It was physically impossible to scoop out all traces where there was extensive tuberculous disease. The mode of treatment which he advocated was not to be adopted indiscriminately, but only in selected cases, and in the early stages of the disease. Whatever had been said to the contrary, there was no one more alive than he was to the importance of the most perfect rest that could be obtained by mechanical and other means in the treatment of joint-disease.

MR. W. THORNLEY STOKER also replied. With regard to the caustic or no caustic question, he had expressed and felt no very strong opinion. He believed in bone-drainage, and, as stated in his paper, he was open to conviction on the subject of caustic one way or the other. Like Mr. Stokes, he regarded rest as a most important adjunct of the treatment which he advocated. Although Mr. Franks spoke from an Olympian height of modern pathology, he was not carried away either by the positiveness of Mr. Franks' statement or the cogency of his argument; and despite his having decried the division into osteal and synovial cases, he still thought that was the most important clinical division of morbus coxæ that could be made. Upon that he based the value of the treatment which he advocated. He had not overlooked the distinction between tubercular and simple disease. He had mentioned it, but in addressing a learned society it was unnecessary that that subject should enter into the text of his paper as if he were addressing a number of first-year students. He did not believe all cases of morbus coxæ were tubercular, while he was sure a great number of them were.

---

*TWO TRACHEOTOMIES ON THE SAME DAY IN ONE FAMILY—WATER POURED INTO TRACHEAL WOUND TO ASSIST EXPECTORATION.*

At a meeting of the Practitioners' Society of New York, held April 2, 1886, DR. GEORGE F. SHRADY referred to two cases of tracheotomy which he had recently performed on the same day upon two sisters, aged respectively 2 and 4 years (*Medical Record*, June 19, 1886). He was called to them the day previous to the operations. They were both affected with diphtheria. In the younger the disease was in the fauces and extended downward, and in the older it was confined to the larynx and trachea. Both rapidly developed symptoms of suffocation.

The temperature in the younger child was 102° F., and in the older 101° F. The operations were performed without mishap, first upon the younger sister, and in a few hours after upon the older one. The younger, although temporarily relieved of the difficulty of breathing, died of secondary croup twelve hours afterwards. The older child recovered, discharging through the tube on the fifth day a bifurcated fibrinous cast. In neither of the cases was any chlorate of potassium or iron administered, the treatment consisting in the

freest possible stimulation by milk-punch. The latter, he remarked, was his mainstay in desperate cases. This opinion was shared by Dr. Ripley, who saw these cases in consultation, and assisted at the operations.

There was one item in the after-treatment to which he wished to call attention.

There was, as is usual, a great deal of expectoration through the tube, which was assisted by the inhalation of steam. But the most prompt benefit was derived from pouring lime-water by the teaspoonful directly into the trachea through the wound. This was done at the suggestion of Dr. Ripley, who had frequently used it in his practice with occasional good result.

Dr. Shrady had never seen this method tried before, and was struck by its good effects in dislodging tough mucus and shreds of membrane.

DR. BALL said he was unable to see how the lime-water could be of any special service, as it was expectorated so quickly, and thought that plain water would be equally as good.

DR. SHRADY said that, so far as the mechanical effect was concerned, water would answer the same purpose. The possible advantage of the lime-water was, that in case any was retained, it might have the effect of loosening the phlegm, or of possibly helping the separation of membrane.

#### THE TREATMENT OF NEURALGIA BY PARTHENINE.

DR. ESPERON publishes the notes of two cases of neuralgia treated by parthenine, an alkaloid recently extracted from a plant which is known in Cuba as *giesta amara* (*Les Nouveaux Remèdes*, April 1, 1886). The first was that of a woman, aged 33 years, who, as a consequence of an abortion, suffered from very severe pains in the iliac fossa during the menstrual period. Morphine, chloral, bromide of potassium, were all inefficacious, but quinine somewhat relieved the suffering. In a subsequent attack, characterized by pain, chills and fever, the author diagnosticated ovarian neuralgia. He made a subcutaneous injection of morphine, and gave 1 grain of parthenine every two hours. The effect of the morphine was evident an hour after its administration, but the pain, nevertheless, continued. As a consequence of three doses of parthenine, the pain disappeared, and did not return. The same effect was obtained in another case. The author claims that this

substance is especially indicated in neuralgia of malarial origin.

#### A NEW METHOD FOR THE REMOVAL OF INTRAMURAL UTERINE TUMORS.

DR. O. STROINSKI, of Chicago, writes to the *New York Medical Record* (June 19, 1886) as follows: "After severe losses in removing intramural uterine tumors through the abdominal or vaginal walls, I decided either to abandon entirely any attempts of extirpation of these tumors, or to find a method that would give a reasonable show of favorable results. Lately I have found that continued intra-uterine injections with diluted subsulphate or sesquichloride of iron produce a discharge of mucous membrane, as well as of muscular stratum, and that, combined with the effect of contractions always evoked by these injections, causes the intramural tumors to be forced into the uterine cavity, where they may easily be seized and extracted. I will give the minute details of these proceedings at another time, and will now merely formulate the conclusions which I have arrived at after a careful study and a good deal of experience: 1. Extirpation of intramural uterine tumors through the abdominal or vaginal walls is as unnecessary as it is dangerous; while, 2. There are certain procedures which always transform the intramural into an intra-uterine tumor, which can be easily extirpated; 3. These procedures only should be made use of in the removal of intramural tumors, being entirely harmless, and never endangering the life of the patient nor maiming the sexual organs; 4. Even the largest myoma might be easily removed by this operation; 5. Only tumors situated on the surface of the uterus are excluded from this procedure. I have operated on cases in which large doses of ergot had been taken for a long time without the slightest effect, and in one case in which the tumor had existed before marriage, and a child had been born without the tumor losing its size or changing its position. I will furthermore say, that I have operated in private as well as hospital practice, so that there cannot be any doubt of the reality of the facts."

#### URETHAN IN THE TREATMENT OF TRAUMATIC TETANUS.

MR. W. T. JACKMAN reports in the *Lancet* for June 12, 1886, a case of a boy, aged 15 years, who came under his care with well-

marked symptoms of tetanus, as the result of a crushing of a finger by cog-wheels five weeks previously. The lockjaw was complete, and the opisthotonos well marked; severe paroxysms of pain were complained of, which were greatly exaggerated at night. The patient had noticed his neck and jaw muscles gradually becoming stiff for the past few days, but attributed this to a chill. Chloral hydrate in 20-grain doses every three hours was ordered. This relieved the paroxysms of pain slightly during the day, but the lockjaw, opisthotonos, and rigidity of the muscles of the legs remained the same, and the pains were just as severe and frequent during the night. Fluid nourishment was administered and the chloral treatment continued until March 25, when, as no abatement of the symptoms was apparent, after consultation, it was decided to discontinue the chloral during the night, and in its place give the patient 4 grains of urethan every two hours, from 6 P.M. to 6 A.M. The first night of this treatment showed a marked decrease in the severity of the symptoms, and the patient made gradual and uninterrupted progress until April 20, when his recovery was established. The failure of the chloral hydrate to relieve the severe symptoms during the nights, and the well-marked improvement under the influence of the urethan, seem to point to the latter being likely to prove a very valuable drug in the treatment of tetanus, either prescribed alone or as above in conjunction with chloral hydrate.

#### THE ACTION OF FATTY BODIES ON CARBOLIC ACID.

Fatty bodies have a remarkable effect when mixed with carbolic acid, an effect well known to surgeons who employ carbolized oil containing 1 part in 10 of the acid without pain or irritation, whereas 1 part of the acid to 40 of water produces a distinctly irritating effect. This property appears to belong to all the fatty bodies as well as to glycerin, and carbolized soap, containing 1 in 10 of the acid, is also well borne. PERIER has pointed out that only the crystallized acid being so affected, the use of any other form of acid is attended by the usual irritation. Experiments were made with the view of ascertaining whether vaseline had a similar effect, but this was found not to be the case, and if a vaginal examination be made, the finger being anointed with vaseline containing 1 in 20 of the acid, the patient will complain of a burn-

ing pain. The question naturally arises as to whether the antiseptic properties of the acid are lessened by the addition of oils at the same time as its irritating qualities. The result of clinical experience seems to prove that this is not the case, and the benefit of a stronger solution in oil may be obtained without the inconvenience of any caustic action.—*Medical Press*, June 9, 1886.

#### CHRONIC CATARRHAL GASTRITIS.

At the recent meeting of the Association of American Physicians, held in Washington, DR. FRANCIS DELAFIELD, of New York, read an elaborate paper on "Catarrhal Gastritis" (*Boston Med. and Surg. Journ.*, June 24, 1886).

In the consideration of the treatment of the disease he brought out many new points.

In attempting to establish a satisfactory treatment for chronic gastritis, he shows that it is important to state as clearly as possible the problem which is to be solved.

First, then, we must remember that all the patients who suffer from gastric symptoms do not necessarily have chronic gastritis.

Besides those who have functional disturbance of the stomach, or cancer or ulcer of the stomach, we find many others in whom gastric symptoms are due to diseases of other parts of the body. Anæmia, uterine disease, the neurotic and hysterical condition, and constipation, often behave in this way. In old people, the function of gastric digestion is often impaired simply as the result of old age. To each one of these conditions belongs its appropriate treatment, but it is not the treatment of chronic gastritis.

Still further, we must remember that in many cases of gastritis, palliation of the symptoms is all that we can hope for. This is true with the gastritis associated with heart-disease, emphysema, phthisis, cirrhosis, Bright's disease, gout, rheumatism, and alcoholism. It is also true of the cases in which the inflammation has gone on to the destruction of the septic and mucus glands. After excluding all these, there remains a large and important group of cases of chronic catarrhal gastritis, in which we may hope not only to alleviate the symptoms, but to cure the disease.

It is evident, from the nature of the disease, that any treatment intended not merely to palliate, but to cure, must be of long duration, and that it must be repeated from time to time, when the inevitable relapses occur.

The different plans of treatment, then, which may be adopted are—

The curative effects of climate and mode of life.

The regulation of the diet.

The administration of drugs.

The use of local applications directly to the inflamed membrane.

#### I. CLIMATE AND MODE OF LIFE.

The two points of importance are,—first, the locality selected must be one where the patient can lead an out-of-door life; second, the patient must live in this climate either for several years, or for a considerable part of each year.

Excellent as this method of treatment is, it is evident that it can be carried out only by a limited number of persons.

#### II. THE DIET.

The regulation of the diet is a matter which demands consideration in every case of chronic gastritis. In trying to ascertain the best way of feeding these patients, he has found only one satisfactory method, and that is to feed them experimentally with different articles of food, and then, after an interval of several hours, wash out the stomach, and see how thoroughly these articles of food have been digested and removed from the stomach. After pursuing this course for a number of years, Dr. Delafield has arrived at the following conclusions:

It is necessary that the patient should be well fed; a starvation diet never answers.

The stomach does not require any rest from the performance of stomach digestion; on the contrary, it is all the better for being called on to perform its natural functions.

The patients' own ideas as to what food agrees with them are usually erroneous. They are apt either to starve themselves or to select the least nutritious articles of food.

The use of artificially-digested foods, or of substances such as pepsine to assist stomach digestion, is unnecessary.

The starches, oatmeal, cornmeal, bread, the cereals, the health foods are, as a rule, bad. Portions of them remain undigested in the stomach for many hours.

Milk in adults is an uncertain article. It answers very well for some persons, not at all for others.

Meat is usually readily and well digested, but there are occasional exceptions to this rule.

Vegetables and fruits can be eaten, but the

particular varieties must be selected experimentally for each patient.

He does not believe that any case of chronic gastritis is to be cured by diet alone. Even the exclusive milk diet, while it often relieves symptoms, is, as a rule, only temporary in its effect, so that the patient simply loses a certain amount of time by employing this instead of more efficacious plans of treatment.

#### III. THE ADMINISTRATION OF DRUGS.

The advantageous use of drugs belongs to the earlier stages of chronic gastritis. At that time they often palliate symptoms, and sometimes even seem to cure the inflammation. In the later stages of the disease their use becomes more and more unavailing. The reliable drugs for this purpose are not numerous,—the preparations of soda, potassium, and bismuth, the mineral acids, glycerin, sometimes carbolic acid, sometimes iodoform, sometimes the bitter infusions. If none of these answer, it is hardly worth while to look any further. If we can combine, with the administration of drugs, the regulation of the diet and of the mode of life of the patient, then, of course, our chances of success are much greater.

#### IV. THE USE OF LOCAL APPLICATIONS MADE DIRECTLY TO THE MUCOUS MEMBRANE OF THE STOMACH.

This the author regards as the most efficacious plan of treatment for those patients who are not able to leave home and seek a proper climate, but ask to be relieved without interruption to their ordinary pursuits. The local applications are readily made by the introduction of a soft rubber tube through the œsophagus into the stomach.

Liquid applications are the best. They should be made in such quantities as to come thoroughly into contact with the entire surface of the mucous membrane, although the pyloric end of the stomach is the region where the inflammation is principally situated. They should be made at a time long enough after eating for the stomach to be as nearly empty as possible.

For many cases warm water alone in considerable quantities is the only local application needed. In some, however, there is an advantage in medicating the water, and for this purpose he employs a variety of substances.

The alkalies, the mineral acids, bismuth, carbolic acid, the salicylates, iodoform, bella-

donna, ipecac, gelseminum, may each one be employed according to the particular case.

For the first week it is often necessary to put the patient on a milk diet, and this can be done even with those patients who, under ordinary circumstances, cannot take milk at all.

Then, after a time, to the milk we add one solid meal composed of meat alone. Next, this single meal is increased by the gradual addition of fruits, vegetables, and bread. Then comes the giving of two solid meals a day instead of one, then three solid meals, and now we get rid of the milk in part or altogether.

For the first week of this treatment it is wise not to expect any special improvement. Indeed, even a longer time than this may try the perseverance of the physician and the confidence of the patient.

Sooner or later, however, the expected improvement begins,—the nausea and vomiting cease, the constipation or diarrhoea is improved, the flatulence is no longer troublesome, the headache becomes less frequent, and, of more real value than these, the improvement in the general condition of the patient becomes evident. The color, the weight, the appetite, the sleep, the spirits of the patient, all show a change for the better. Of all the symptoms, the pain is the one which is apt to persist the longest.

For two or three months the patient has to be kept under observation, and the applications to the stomach made by the physician. After this the patient is dismissed, but continues the treatment himself, first every other day, then twice a week, then once a week for several months. The regular relapses of the disease are managed in the same way, but are much more quickly relieved.

#### THE DIURETIC ACTION OF CLODBERRIES AND WATERMELON.

In the course of a prolonged study of diuretics, PROF. S. A. POPOFF, of St. Petersburg (*Vratch*, No. 4, 1886, p. 34), examined the action of three remedies used as diuretics in Russian popular medicine; they were cloudberrries (*Bacca Rubi Chamæmori*; Russian *moroshka*), watermelon (*Cucumis citrullus*; Russian *arbooz*), and dew-worms (*dojdevyi tchervi*).

1. *Cloudberrries* are used chiefly by peasants in Northern Russia, in the shape of an infusion of the berries in water or vodka (*aqua vitæ*). Scientific medicine contains but scanty

fragmentary notes on the drug; thus, Dr. Trinkovsky (*Medits. Zeitung Russlands*, No. 44, 1856) stated that he successfully employed the infusion as a diuretic in a case of hydrocephalus in a child. Dr. Popoff first prepared a decoction and extract of the fresh berries, and then—after a series of experiments on man and animals had convinced him of the really powerful diuretic action of the drug—proceeded to isolate its active principle, after the method given by Prof. A. A. Loesch for the extraction of blattic acid from cockroaches. He obtained in that way an acid in the shape of an almost colorless powder, easily soluble in spirit of wine, but very sparingly soluble in water. It gave crystallized and easily soluble salts with alkalies. Experiments on cold- and warm-blooded animals showed that the acid, like antihydropin (blattic acid), belonged to the class of "essential diuretics" (that is, drugs which act solely on the renal tissue); for, on its subcutaneous or intravenous introduction even in very large quantities, it did not give rise to any considerable changes either in the cardiac action or in the arterial tension. The diuretic action of the acid was manifest under all methods of introduction into the system, but the strongest effects were observed on intravenous injections (of 2 centigrammes of the sodic salt for each kilogramme of the animal's weight). Division of the spinal cord, of the splanchnic nerves, curarization, etc., increased the diuretic action of the drug. Stimulation of the splanchnic nerve did not diminish the secretion of urine. But, while fully recognizing that cloudberrries are a good and safe diuretic, the author yet comes to the conclusion that, as such, they are considerably weaker than antihydropin and cannot replace the latter.

2. *Watermelon*.—This, by the way, was recommended by Prof. V. A. Manassein, in the *Vratch*, November, 1881, p. 351, as an extremely cheap, but effective substitute for grapes in the treatment of chronic congestion of the liver, chronic intestinal catarrh, etc. It is extensively used by the peasantry in Southern Russia (especially near the river Don, and in the Caucasian districts) in the form of the freshly expressed juice, as a diuretic draught in cases of dropsy, uro-genital affections (especially gonorrhœa), etc. The author experimented with the inspissated fresh juice or syrup of the fruit, and with commercial melon-honey (*arbooznyi miod*). The diuretic action proved most striking: when animals received from 50 to 100 grammes of the syrup (with food) in twenty-four hours, the daily quantity

of urine was three or four times greater than under ordinary conditions; again, on intravenous injection of the syrup, "the urine for several minutes flowed in a stream from a canula tied into the ureter." On the subcutaneous injection of 0.4 to 0.7 gramme into frogs, the syrup rapidly slows the cardiac action up to complete arrest in diastole, and produces prostration with loss of voluntary movements, while reflex action and the excitability of the motor nerves and muscles remain intact. When very large doses are used, in the latest stages there is observed, also, a failure of reflexes and of nervo-muscular excitability; but the phenomenon is then undoubtedly nothing but an ordinary symptom of præmortal agony. In dogs, the internal administration of 500 grammes at a time produces no effect, except powerful diuresis. Intravenous injection of 1 to 2 grammes of the syrup causes an immediate increase in the secretion of urine, the latter assuming a dark color, and containing sugar. This increase lasts for ten to sixty minutes, and is accompanied only by a slight fleeting decrease of the blood-pressure. On the injection of 0.25 to 0.5 gramme for each kilogramme, a considerable fall of the pressure and a great acceleration of the pulse rapidly follow. An intravenous injection of 3.0 grammes per kilogramme produces a further fall of the pressure and a fleeting increase, with a subsequent sudden enormous decrease in the frequency of the pulse, the animal dying from cardiac paralysis. As some special experiments show, the quickening of the cardiac action is dependent upon the syrup acting on the peripheral ends of the vagi. In all cases, intravenous introduction of the syrup rapidly produced a strong sedative effect, "the animal remaining strikingly quiet, and giving no response to tactile or even pathic irritation." Another group of experiments showed that the diuretic action of melon-syrup was dependent mainly upon its direct influence on the renal tissue.

3. *Dried dew-worms* are used by Russian peasants (especially in the Smolensk Government) in the shape of a powder or an infusion. They, also, possess a decided diuretic action, as will be shown in a forthcoming work of Dr. Shimansky, who is now studying, under the guidance of Prof. Popoff, the physiological properties of this palatable drug.—*London Medical Record*, June 15, 1886.

#### A NEW AND ORIGINAL METHOD OF SURGICAL DRESSING.

DR. CHARLES W. STROBELL, of Middletown Springs, Vermont, writes to the *Medical Record*, June 26, 1886, that he was led by the paper of Dr. Hamilton and the criticisms upon it in recent numbers of the *Record* to consider what improvements might be made upon the modes of antiseptic dressing now in use. The main objection to the ordinary dressings of cotton-wool, gauze, etc., is that it conceals the wound from view, so that inflammation, secondary hemorrhage, and other accidents cannot be detected at their onset, and may become only too well established before the surgeon becomes aware of their existence. In order to obviate this, Dr. Strobell proposes to cover the wound with a thin glass globe, so constructed as to fit closely to the part, provided with two openings for drainage-tubes and a large opening on the top to permit of access to the wound in case of need, without removing the globe. These openings are provided with glass stoppers, so that they can be hermetically closed. The base of the globe is provided with a flange, and its sides, up to within two inches of the drainage-tube openings, are roughened so as to facilitate the adhesion of the isinglass plaster used in sealing it. When applied to stumps after amputation, a thin rubber band, three inches wide, is applied over the flange, so that it rests with one-half its width on the integument of the limb to secure additional safety. The flange is covered on its external surface with isinglass plaster adhesive on both sides, so that the band of rubber shall adhere firmly to the globe. In the case of an amputation at the knee-joint, after the sutures and drainage-tubes are in place, the wound is capped with a disinfected globe of the proper size to fit snugly over the limb, the drainage-tubes in the globe being on a line with the anterior surface of the wound. The rubber band is now turned down over the limb, and strips of adhesive silk, one inch in width, and twelve inches in length, are applied longitudinally from the upper part of the ground portion of the globe up the limb, each strip overlapping slightly the preceding one, a final strip being placed circumferentially around the flange and covering in the ends of the longitudinal ones. In a case of laparotomy an oval-shaped globe may be applied in a similar manner.

The following are the conclusions of the writer: "The method commends itself to the profession,—1. In the complete isolation of wounds that can be obtained in the event of

infection of hospital wards by erysipelas, etc., as the globe can be hermetically sealed. 2. All changes can be noted clearly at any moment with the minimum amount of discomfort to the patient, thereby increasing largely his chances of recovery. 3. The perfection of drainage, which has never been obtained in so great a degree, obviating the necessity of soaking off bandages saturated with dried pus, blood, and serum, often adhering so firmly to the wound that the most gentle manipulation is required to avoid laceration of the tender granulations. 4. Secondary hemorrhage can be detected at the earliest possible moment. 5. The first evidence of inflammation can be noted, and its movement forestalled by removal of the cause. 6. The action of topical remedies can be observed without exposure of the wound to the air. 7. The dressing can be adapted to wounds of almost every description. 8. Refrigerant and thermal water-dressings can be applied with the utmost facility. 9. Lotions or powders can be easily applied to the wound through the main opening in the globe without disturbing the dressings. 10. If it is desired to prevent the ingress of infected air, the drainage-tubes can be filled with plugs of iodoformed or carbolized cotton. 11. In the event of inflammatory swelling rendering the constriction of the base of the globe excessive, the apparatus can be replaced by one of larger size, with less expenditure of labor and time than is required in the application of a Lister dressing. 12. Facility is afforded for determining the therapeutic effect and germicidal action of direct sunlight in the treatment of wounds. 13. By means of long, slender forceps and scissors the sutures, drainage-tubes, and adhesive plaster may be easily removed through the main aperture in the globe. 14. The weight of the apparatus is not as great as that of the ordinary Lister dressing. 15. If perfectly applied there should be no more constriction of the limb than results from moderately firm bandaging. 16. The expense is comparatively light, as the globes can be used indefinitely, being thoroughly disinfected by boiling water. 17. The apparatus may be adapted to any external surface by taking, in special cases, wax impressions and transmitting them to the manufacturer. In conclusion, I will say that my claim to originality is, in my opinion, well founded, as nowhere in surgical works have I seen glass mentioned, used in the way I have indicated, as a protective dressing."

## Reviews.

THE INTERNATIONAL ENCYCLOPÆDIA OF SURGERY.  
 Edited by John Ashhurst, Jr., M.D. Vol. VI.  
 New York: William Wood & Co., 1886.

This, the sixth and last volume of the *Encyclopædia*, completes the labor of its editor, Dr. Ashhurst, who has, he writes, been engaged in the task for more than six years. We congratulate him upon the termination of his work, and feel confident that he has built for himself a monument which will ever remain as an evidence of his industry, perseverance, and learning. The present volume contains contributions from writers who represent several nationalities, and is, therefore, a true international volume.

The article on "Injuries and Diseases of the *Œsophagus*" is by Dr. J. Solis-Cohen; it also includes a section on "Gastrostomy and Enterostomy." The writer has given a full, clear, and practical monograph upon these subjects. Many of the lesions of this portion of the digestive tract are found to be beyond the power of the surgeon to cure, yet various methods of relieving pain and prolonging life have been devised. Dr. Cohen has made a most thorough investigation of the literature of these affections, and has given us all worth knowing of their diagnosis and treatment.

Dr. John Ashhurst, Jr., contributes the article on "Intestinal Obstruction." This affection was formerly almost exclusively confined to the domain of the practice of medicine, but from the advances which have been made in modern surgery, it has now become one of great importance to the surgeon, and operative interference has a just, indeed an imperative, claim in this lesion. The different forms of intestinal obstruction, their symptoms and diagnoses, are given in a most concise and able manner by Dr. Ashhurst; in fact, we cannot conceive any one failing to readily comprehend the descriptions given by him. The surgical features of the lesions are more especially dwelt upon by the writer, and there remains but little for the reviewer to notice except to praise. The antiseptic method of operating in laparotomy is not advised, although the author can see no harm in the surgeon adopting Listerism, without the spray, "if he thinks that by so doing he renders the operation safer to his patient." Keith and Tait, of England, are quoted as opposed to the Lister method. Again, it is stated that the mortality of the operation has increased since the prevalence of antiseptic surgery. It is

upon this most important part of the technique in laparotomy that we must differ with Dr. Ashhurst. The surgeon who would undertake to perform the operation of opening the abdominal cavity without employing antiseptic precautions,—not Listerism as understood by many, but Listerism as meaning aseptic measures,—we believe does so thinking he is doing the best for his patient; but, in our judgment, and in that of those who have had a large experience in this class of operations, the neglecting to use all measures that have been found by the majority advantageous to success, is not doing the best for the patient. Both Keith and Tait we consider to be the best exponents of aseptic surgery; indeed, the minuteness of technique practised by these operators, in order to carry out as near as possible an ideal aseptic condition, can scarcely be excelled. An increase in the mortality of about two per cent. is observed in the statistics given by Dr. Ashhurst, taken from his former table published in 1874, and his present one, from which he concludes that antiseptic surgery has not diminished the fatal termination in this operation. That there has been an increase in the number of deaths during this period of ten years is not at all to be wondered at; in fact, when it is recognized that the frequency of the operation has increased fivefold during this period, we can only congratulate ourselves upon the advance in surgery which has encouraged surgeons to attempt an operation that formerly had been so seldom undertaken. To censure antiseptic surgery for the increased mortality we believe to be unjust, and we cannot but think that Dr. Ashhurst upon this point is in accord with us.

"Injuries and Diseases of the Rectum," by William Allingham, F.R.C.S. This surgeon, so well known as a writer upon these affections, has written a somewhat brief, but decidedly instructive, and in no way speculative article. It is evident that personal experience and great familiarity with these lesions have given the author the necessary training to write as he does, and his advice in the treatment of these diseases can generally be followed without hesitation. The section on the anatomy and physiology of the rectum is especially worthy of notice, and its study will greatly assist in more readily understanding the different pathological changes, and to more correctly apply means for their relief. We find it stated that cases of stricture of the rectum and ulceration not cancerous are considered to be due to tertiary syphilis, and are

not the result of contamination by the discharges from chancroids. In this we believe the writer to be in the right, and although most surgeons are opposed to his view, we think a careful investigation of these cases will demonstrate their error. The section on hemorrhoids includes all the surgeon may require to diagnose and to treat these very frequent lesions. Preference is given to the crushing operation, but in certain cases the ligature is to be used. The injection of carbolic acid, caustics, or astringents, the removal with the *écraseur*, the application of acids, the galvanic cautery, the clamp, and actual cautery are all said to "have little to recommend them; when they are not uncertain methods they are dangerous, and occasionally they combine both danger and uncertainty of result." To all of which we agree, making, however, an exception in favor of the clamp and actual cautery. This method we have followed for several years, and the results have been very successful.

Dr. E. L. Keyes has written the article on "Urinary Calculus," and we are most favorably impressed with the way in which he has presented the subject. The causes, geographical distribution, classification, structure, both chemical and gross, and different locations where urinary calculi may be met with are all given in a masterly manner. Turning to the section that discusses stone in the bladder, the most important and most frequent of urinary calculi, we find that the writer does not disappoint our expectations. While other surgeons have been duly accredited with their labors in this field, and their work fully appreciated, Dr. Keyes has also written freely of his own personal experience and observations. It almost seems as if the diagnosis and treatment of this affection were about as near perfection as surgeons may reasonably hope for. Indeed, Dr. Keyes writes, "My general impression is that the operation is reasonably (but not entirely) safe, even where the kidneys are unsound, and that with perfectly healthy kidneys litholapaxy, properly performed, is nearly as harmless an operation as passing a catheter." A method of diagnosis by means of the Bigelow apparatus for washing in litholapaxy, in which the striking of the most minute particle against the tube may be felt by the surgeon, has proved in the hands of Dr. Keyes successful when all other means had failed. The suprapubic operation is fully described, including the more recent method advocated by Petersen, in which the distended bladder is lifted

out of the pelvis by forced dilatation of the rectum, thereby removing greatly the danger of injury to the peritoneum. This is the operation which has lately been so favorably presented by Sir Henry Thompson; indeed, he is inclined to believe that the future operations for stone will be limited to this suprapubic one and that of litholapaxy. The conclusion of Keyes is, however, not so favorable. He writes, "My conclusion from the evidence, therefore, is that the high operation (suprapubic) is suitable for the management of very large stones, for encysted stones, for stones complicated by tumors of the bladder, and for certain foreign bodies, but that it is not appropriate for general application." The section on litholapaxy is quite exhaustive and excellent. The directions for manipulating the instruments in performing this operation are given so very clearly that one cannot fail to fully understand them, and it is very evident that the writer is speaking from actual experience. The selection of a method of radical treatment in cases of stone is at times a perplexing question for the surgeon to decide. Dr. Keyes, from his experience, has reached the following conclusions as to the cases in which lithotomy is to be preferred:

"1. All male children before puberty.

"2. All cases complicated by very severe chronic cystitis.

"3. Cases of tumor of the bladder complicating stone.

"4. Some cases of prostatic overgrowth not complicated with atony.

"5. Some cases of very large prostate through which instruments cannot readily be made to pass.

"6. Cases complicated by severe deep urethral stricture.

"7. Cases of very large or very hard stone.

"8. Cases of encysted stone.

"9. Cases of certain foreign bodies.

"All other patients who are proper subjects for radical operation may be best dealt with by lithotripsy; very small stones possibly by the old-fashioned operation without ether, perhaps with cocaine, but all other calculi by litholapaxy."

Professor Hingston's contribution on "Lithotripsy" is a most admirable paper, full of sound advice and practical observations. The writer is an ardent advocate of this operation, and believes it to be the one which will eventually supersede all others, since for him age, condition of the bladder and kidneys, or urethra are equally suitable either for lithotripsy or lithotomy. He, however, cautions

against reckless operating, more especially in the use of the evacuating instrument. "Rapid lithotripsy, conducted with care and prudence, and with due regard to the patient's general and local condition, is a most satisfactory procedure; but rapid lithotripsy, when it means the invariable completion of the operation at a single sitting, may mean suffering, disaster, and death."

"Injuries and Diseases of the Bladder and Prostate," by Reginald Harrison, F.R.C.S. This article, coming from the pen of so celebrated a writer upon genito-urinary surgery, should entirely satisfy the expectations of all, and, indeed, it is a valuable contribution. The section on hypertrophy of the prostate may be read with benefit by all surgeons, and although the author can suggest no preventive treatment, yet we think him in the right when he advocates early dilatation of the prostatic portion of the urethra. It is to us certainly rational to believe that so soon as any obstruction to the passage of the urine is manifest, an attempt to keep the canal open by means of bougies is the proper course to adopt, and the experience of Mr. Harrison would seem to justify such a conclusion.

The operation of "Prostatotomy" is recommended by Mr. Harrison in cases of hypertrophy of the prostate where there is unusual difficulty in passing the catheter. "It consists in opening the membranous urethra from the perineum, making a section of the obstructing portion of the gland in the median line." A drainage-tube of special form, devised by Mr. Harrison, is introduced through the opening into the bladder, and retained in position from six to twelve weeks. The results obtained by this method of treatment have been such as to encourage the adoption of the operation by Mr. Harrison in several cases. In an affection where the suffering is so great that life is scarcely worth living,—and truly such is the case in some of the long-standing cases of hypertrophy of the prostate,—any means which offers the faintest hope of relief from such misery is justifiable, and it becomes the duty of the surgeon to perform any operation that may possibly allay suffering. Under tumors of the bladder we find no reference to the digital exploration of this organ through incision of the urethra from the perineum,—a method which has been so successfully employed by Sir Henry Thompson; and as there is usually great difficulty in forming a correct diagnosis in these cases, any procedure that is at all likely to aid us ought not to be neglected.

Professor Simon Duplay has written a very exhaustive and most excellent treatise on "Injuries and Diseases of the Urethra." The article discusses exploration, traumatism, foreign bodies, organic lesions and malformations of the urethra, and urinary fever. The section on stricture of the urethra is entirely a French view of this lesion: English or American surgeons who have contributed any information—and they certainly have done much in this field—are neither quoted nor referred to. M. Duplay, we believe, is in the right when he writes, "Finally, it cannot be too often repeated that the cure of stricture of the urethra is never radical and final, no matter what method of treatment may be employed; and that relapses will inevitably occur if care be not taken to maintain the results obtained by means of treatment continued, so to speak, indefinitely." This opinion, however, is contrary to the opinion held by Otis, who claims that the cure is permanent when the operation as proposed by him is adopted. The methods of treatment in this lesion, proposed by M. Duplay, are either cauterization, dilatation, or urethrotomy. Cauterization is a procedure not advised by English or American surgeons of to-day; yet, in the opinion of M. Duplay, in certain cases it answers a good purpose. It is only to be resorted to, according to him, as an auxiliary to dilatation, never should be deep and destructive, and preference should be given to cauterization practised from before backwards. Dilatation is the method most approved of by M. Duplay. The Voilemier division into inflammatory and mechanical dilatation is adopted by him. The former is understood by English and American writers to be continual dilatation, and the latter known as gradual and rapid dilatation. Inflammatory dilatation, and the pathological phenomena which this treatment occasions, are fully described, and it is thought to this method "the first rank should without contradiction be accorded." Mechanical dilatation is divided into gradual, rapid, forced, sudden, and forced injection. Of these methods, M. Duplay gives the preference to gradual dilatation when applicable, and sudden dilatation or divulsion is, from his own experience, thought to have the advantage of giving better results than internal urethrotomy. This opinion is not accepted either by English or American surgeons, who almost without exception concede the advantage to internal urethrotomy over divulsion; indeed, the latter operation is seldom advised by them, and a few consider it to be a dangerous method. The section on

"Spasm of the Urethra" is worthy of special notice, especially as this symptom is rarely so fully discussed in English or American works which treat of these diseases. Malformations of the urethra is the one section of all others included in M. Duplay's article which should be carefully studied by surgeons who may have occasion to perform any operation to remedy these defects. The methods proposed and practised by him seem to be most admirably adapted to cure these lesions, and his results appear to have been very satisfactory. Of the various theories advanced to account for the development of urethral or urinary fever, M. Duplay believes that that of "phlebitis and nervous exhaustion belong to history, and are absolutely untenable; there remain the theory of direct absorption and the renal theory; equally rational, equally in accord with recent advances relative to the pathological physiology of fever, they both make urinary fever the result of a systemic intoxication with the constituents of the urine; the first admits the resorption of these constituents by a point of lesion in the urinary passages, the second maintains their non-elimination by a chronically altered kidney, or by one the function of which is temporarily disturbed by a passing congestion of reflex origin." In deciding between these two theories, we are inclined to think with M. Duplay that both are concerned in producing two very different forms of urinary fever, one an acute or rapid, the other chronic or slow. To the former the reflex theory seems to us most applicable, and the resorption theory to the latter.

"Injuries and Diseases of the Male Genital Organs," by H. Royes Bell, F.R.C.S., includes injuries and diseases of penis, affections of scrotum, hydrocele, hæmatocele, varicocele, anomalies of testis, affections of cord, injuries of testicle, orchitis, tumors of testicle, and functional disorders of male genital organs. Very concise and thorough descriptions of these various diseases are given, and the sections on "Tumors of the Testicle" and "Functional Disorders" are especially worthy of careful reading.

Professor Parvin has written a very excellent paper on "Injuries and Diseases of the Female Genital Organs." It includes the pathological changes, traumatism, and functional lesions of these parts that may demand surgical treatment for their relief or cure. Emmet's operation for laceration of the cervix uteri is thought well of in suitable cases by Professor Parvin, but it is not to be un-

necessarily resorted to. He writes, "While the mortality is not great, in view of the important benefits which this procedure confers when employed in suitable cases, and while proper precautions will no doubt very much lessen this death-rate in the future, it is important that the operation should not be regarded as entirely devoid of danger, and thus rashly advocated or recklessly performed." Perineal lacerations are very fully discussed, and we think with Professor Parvin that it is good surgery, when such lesions do occur, to perform the immediate operation. The very formidable operation of extirpation of the entire uterus, in cancer of this organ, we have always regarded as scarcely to come within the limits of justifiable surgery; yet the operation has its advocates. Professor Parvin writes concerning it, "Extirpation of the uterus for cancer is being so frequently done, at least abroad, and is, if not beginning to be more generally received as a legitimate operation, at least so much less decried than it was at first, that the vaginal method of its performance will be given."

The paper by Dr. Robert P. Harris on "The Cæsarean Section and its Substitutes; Laparotomy for Ruptured Uterus and for Extra-Uterine Fœtation" is a most interesting and valuable study of these operations; and all that can be of any assistance to the surgeon, if so unfortunate as to be required to perform any of these operations, he will certainly find in this article. Of the various methods proposed in order to perform the Cæsarean section, Dr. Harris gives the preference to the Porro operation. He writes, "The Porro operation has entirely superseded the old method in most of the lying-in hospitals of Europe, and has reversed their tables of mortality completely. . . . It is true that antiseptic measures, preparative treatment, and early operating have had much to do in effecting this, but there is also a very decided diminution of the death-rate, due to the operation itself."

"Ovarian and Uterine Tumors," by Charles Carroll Lee, M.D. This paper includes ovarian and uterine tumors, oöphorectomy, and hysterectomy. The operation of ovariectomy is very fully described, the directions for its performance quite explicit, and strict antiseptic precautions are insisted upon. Battey's operation is minutely described, the indications for resorting to it are given, and include two main groups,—1. Neurotic conditions from ovarian irritation; 2. Hemorrhage with or without uterine tumors." In regard to the

propriety of performing this operation, Dr. Lee writes, "As to the clinical importance of Battey's operation, it may be said to be still *sub judice*; but, in properly selected cases, each year's experience shows its greater value."

Professor Ollier's paper on "Inflammation of the Bones," although it is one of the briefest in the volume, is, however, one of the most valuable. The subject is treated in a most masterly and scientific manner. More especially is the section relating to the "Influence of Osseous Inflammation on the Growth of Bones, and the Remote Consequences of Acute Inflammations occurring in Infancy and Adolescence," of interest to the surgeon. This phase of the subject has been but little studied, and the practical conclusions drawn by Professor Ollier are of the greatest importance in the treatment of this class of diseases. There is much that we would like to discuss contained in this contribution, particularly the views expressed in regard to the various pathological phenomena which are said to take place in the course of the different inflammatory processes occurring in osseous tissue; space, however, will not permit, and we can only advise a careful reading of the views here found. In writing on the infectious inflammations of bone, Professor Ollier is not yet ready to accept a septic micrococcus as the only etiological factor in this disease. He writes, "However it may be as to the specific character of these microorganisms, which we should not yet either reject or adopt, we shall find in our clinical study of the affection strong reasons to admit a primary infection." The section on the "Treatment of Bone Inflammations," based, as it is, upon a most thorough study of the pathological changes, seems to us to admit of no question as to its correctness, and an adoption of the advice given will rarely fail to be advantageous. Professor Ollier is a firm believer in antiseptic surgery, and an ardent advocate for its employment in bone-operations. He says, "In operations upon man and in experiments upon animals, it is possible nowadays, by means of vigorous antiseptics, to preserve the vitality of bone-tissue after the severest traumas. Formerly necrosis almost always resulted under these circumstances; the wounds became inflamed, and, the vessels of the bone being obliterated, its death was the inevitable consequence."

"Scrofulo-Tuberculous and other Structural Diseases of Bones," by Eugene Vincent, M.D. This article, from the pen of a pupil

of Professor Ollier, is, as would be expected, an interpretation of the advanced views held upon the nature of these lesions. Scrofula and tubercle are considered together on account of the similarity of their pathological histology; indeed, the writer says, "Scrofula is only a mitigated manifestation, initial and usually external, of tuberculosis, and it leads to the latter more or less rapidly." In seeking to ascertain if there is present an infecting agent in tuberculosis, M. Vincent writes, "The general tendency of thought is at present altogether in favor of a parasite, which, in spontaneous tuberculosis, is introduced into the organism by the air-tubes, or the digestive or other passages, fixes itself in the tissues and fluids, the blood especially, and undergoes evolution there, when the soil is favorable to it by a defect of resistance, hereditary, innate, or required." He further adds, "The bacillus (of tuberculosis) might be considered the universal criterion of tuberculosis, and might take the place of the gray granulation, the tuberculous follicle, and the giant-cell. Nevertheless, a conclusion must not be reached too hastily. For MM. Malassez and Vignal have just declared, in a communication to the Société de Biologie, that they have not found any bacilli in lesions which clinical observation and experimentation have shown to be undoubtedly tuberculous; and that they have found in them another form of micro-organism,—micrococci joined in zöoglear masses. There would appear to be, then, a tuberculosis with bacilli and a zöoglear tuberculosis; and I would add, there are still many obscurities to be cleared up, in spite of the progress made. It is evident that clinical observation remains, up to the present time, our surest guide." And, again, in writing on encysted tubercle in bones, he says, "The micro-organism of encysted tubercle is probably not the same as that of tuberculous osteopathies with a more markedly invading and acute course. It may not be the bacillus of Koch; it may be one of its evolutionary forms, either more perfect or less advanced. It is quite reasonable to think that the different forms of tuberculosis depend upon different micro-organisms, or, better still, upon a single parasite with many metamorphoses, and which, according to its soil, goes more or less completely through the cycle of its possible destiny." From these quotations it is evident that the specific nature of tuberculosis is accepted by M. Vincent, and we ourselves have, from our own observations and study of this disease, been

gradually led to believe that the views of those who advocate a micro-organism as the cause of tuberculosis are more in accordance with a scientific understanding, and more capable of explaining the different phenomena of this affection, than any other previously advanced theories. Caries, which has formerly been considered an inflammatory process in osseous tissue and the analogue of simple inflammation in the soft tissues, is placed by M. Vincent among osteopathies which are probably tuberculous. He writes, "The clinical course and the microscopic lesions being the same in caries and tuberculous affections of the bones, we must look to histology and to experimentation for proofs of the tuberculous nature of the former. Histology has discovered tuberculous nodules in caries." He further writes, "It is possible that the parasite may be a different one, and that, in looking for the bacillus, the special micro-organism of caries has not been seen. This point requires further investigation. But we may conclude even now, from what is admitted, that caries is a tuberculous affection of the bones grafted upon a chronic rarefying osteitis." Spina ventosa is also placed in the same class with caries, and considered to be a disease of tuberculous nature. As an evidence of the opinion of M. Vincent in regard to the nature of these bone-lesions, we quote the following: "The more we advance in the study of diseases of bones, the more we see the ill effects of tuberculosis multiply. I am persuaded that the greater number of cases of periostitis and osteo-periostitis, in children and in cachectic adults or old people, are caused by deposits of tuberculigenous parasites, and by their evolution, which varies according to their peculiar nature, the soil invaded, and the part of the soil in which they collect and remain." The section on the "Treatment of Tuberculo-Scrofulous, Osteopathies" demands careful study. Both general and local measures are advised; the former more especially, "since the affection of the bones is only a manifestation of the constitutional vice, hereditary or acquired, which has engendered it." Local treatment is to lend its assistance to the general treatment, and antiseptic precautions are always to be used. We only mention the sections on rachitis, osteomalachia, and fragilitas ossium in order to direct attention to the views of M. Vincent.

Professor Poncet has written the article on "Tumors of the Bones." These neoplasms are frequently a source of considerable perplexity to the surgeon. Their diagnosis is

often very difficult, and their treatment generally demands an operation. A study of Professor Poncet's contribution, we think, cannot fail to assist both in diagnosing and treating this class of lesions.

"Orthopædic Surgery: the Treatment of Deformities," by Frederic R. Fisher, F.R.C.S. This paper includes club-foot, curvature of bones, deformities of lower and upper extremities, lateral spinal curvature, wry-neck, and congenital dislocations. The various forms of club-foot are described in a concise and clear manner. The pathology of this lesion is given, in so far as well-established conditions are known; undecided or disputed points are not discussed. The treatment of the several varieties of club-foot is described in full, and, with few exceptions, we find it judicious and skilful. The directions given for performing the operation of tenotomy are very explicit and clear, but we prefer the employment of the blunt-pointed knife to divide the tendon, after making the incision of the skin and fascia, more often than recommended by Mr. Fisher; it is equally as effective, and not so apt to cause a mishap as the sharp-pointed knife. No reference is made to the treatment of young children by means of manipulation without operation, nor to forced manipulation in bad cases. Both these procedures have given good results, and are very strongly urged by some surgeons. The Adams's modification of Scarpa's shoe is used when applicable by Mr. Fisher in the mechanical treatment of club-foot. This shoe is undoubtedly quite effectual, but very clumsy, and we much prefer some of the lighter and neater American-made shoes. Rickets and curvature of the bones are said to occur independently one of the other. The former exists without the latter, and "children acquire curvature of the bones of the leg who present no indications of the rachitic taint." The weight of the body alone is thought to occasion this deformity by Mr. Fisher.

An appendix is added to the volume, in which are found three very important and ably-written papers,—*"Construction and Organization of Hospitals,"* by Edward Cowles, M.D.; *"Preparation of Military Surgeons for Field Duties, Apparatus Required, Ambulances, Duties in the Field,"* by Bennet A. Clements, M.D., U. S. Army; and *"A History of Surgery,"* from the erudite pen of Dr. George J. Fisher.

To conclude our notice of this volume, we wish particularly to notice the several translations made by Dr. Dulles. He has ren-

dered the contributions of MM. Duplay, Ollier, Vincent, and Poncet into such smooth and even English that the reader does not recognize he is reading a translation, and we feel confident that the ideas of the original writers have been correctly conveyed. The general index, compiled by Dr. Wharton, is also a very satisfactory feature of the book, and adds much to its value. The labor required to complete such a task can only be appreciated by one who has been engaged in a similar work, and we are grateful to Dr. Wharton for so ably doing his laborious task. The volume, as a whole, is in every respect well worthy to be placed among the previous volumes of the *"International Encyclopædia of Surgery,"* and what more praise can we bestow?

### COCAINE IN OPERATIVE SURGERY.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—A few months ago it was said that the most unhappy ophthalmologist in the world was the one who had not written an article on cocaine. It now seems that the surgeon who has not reported a case or two in which he has successfully used cocaine as an anæsthetic on other than mucous surfaces is eking out a very unenviable existence. Therefore, in order that I may enjoy my share of happiness in the future, I desire to report two cases in which cocaine was used with very happy effects.

One, being a case of circumcision, might be very properly termed a mixed case, as the solution was painted on the mucous surface, and also injected hypodermically between the integument and the mucous membrane in the following manner: After painting the mucous surface thoroughly with a four per cent. solution of cocaine, the prepuce was drawn forward and grasped with forceps in the hands of an assistant, when forty drops of the same solution were injected beneath the integument in four different places. After ten minutes the operation was performed in the usual manner, without any pain whatever.

The second case was an ulcerating epithelioma on the dorsal surface of the hand of a gentleman aged 70. An Esmarch bandage was applied from the tips of the fingers to a point midway between the wrist and the elbow, where several turns of the bandage were made around the arm and left *in situ*, while that por-

tion enveloping the fingers and hand was removed, and the tumor, which was circular and one and one-fourth inches in breadth, was freely injected at the base with a four per cent. solution of cocaine, and, after the lapse of twelve minutes, was removed with the scalpel, and the edges brought together with no pain whatever, except as the last suture was being put in; the patient, sitting on a chair, observing the operation and feeling perfectly comfortable, as he himself expressed it.

LEWIS SCHOOLER, M.D.

DES MOINES, IOWA, June 19, 1886.

#### COCAINE IN DYSENTERY.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In a late epidemic of dysenteric flux, confined, in its worst forms, to our river and creek bottoms, under malarial influences, after exhausting my skill in trying to relieve the terrible griping and tenesmus, compelling the sufferer to be up over the chamber every few minutes, I finally made a trial of the hydrochlorate of cocaine, and with great satisfaction. It had the happiest effect, relieving the patient of all pain, and enabling him to drop into a natural and refreshing sleep. I injected 2 to 3 drachms of a four per cent. solution, with a small glass syringe, often enough to give the necessary relief, which about averaged every four hours. I was so much delighted with it, and the profession here take such interest in it, that I thought it might be well to call the attention of the profession to it through the columns of the GAZETTE. I deem it unnecessary to occupy your valuable space in detailing the general treatment of these cases. Will state that while the patients dreaded all other preparations that I injected into the bowel, intended to relieve or palliate their intense suffering, they soon began to beg for the cocaine.

Very respectfully,

R. L. HINTON, M.D.

PRESOTT, ARK.

#### FLUID EXTRACT OF BERBERIS AQUIFOLIUM AND SULPHATE OF BERBERINE AS A SUBSTITUTE FOR QUININE.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—There are so many persons who cannot take the salts of quinine, and so many others on whom they have ceased to have beneficial effects, that in malarial districts it is matter of great importance to have a good

substitute for the preparations of Peruvian bark. After extended observations for three years, I can venture to state that berberine will answer in the place of quinine. It will sometimes do more than quinine in cases of quartan ague. I have used for three years the fluid extract of berberis aquifolium in malarial fevers. To break an expected paroxysm of ague, or remittent fever, or bilious dysentery, I begin twelve hours beforehand, and give a teaspoonful every three hours, until four doses are taken. It acts very freely on the skin, often causing free perspiration, which is sticky, like that caused by the preparations of quinine. Lately I have used for the same purpose sulphate of berberine administered in pills or capsules, the capsules being best, as it is difficult to keep the pills dry. In the same doses, and given in the same way, it will do all that quinine will in malarial fevers. I use quinine when there is no obstacle to its use, as it is cheaper.

I prefer it to quinine in quartan ague, as it is more reliable, and will break the chills after arsenic fails.

Before many years the preparations of berberine will become of great importance in the treatment of malarial fevers, and will rank high as tonics. I hope the profession will test the correctness of my observations, and I feel confident that one trial will result in more.

JNO. BROWN RIGG, M.D.

COLUMBUS, MISS.

#### EXTRACT OF EUCALYPTUS AND GLYCERIN AS A DRESSING FOR ERYSIPELAS.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Recently I have used a dressing of ext. belladonna and glycerin. Last week I substituted ext. eucalypti fluid, for the belladonna, according to the following:

R Ext. eucalypti fluid, part 1;  
Glycerinæ, parts 3. M.

This mixture was applied freely over the eruption, out on to the sound skin, covered in with a pad of cotton, and changed often enough to keep the part thoroughly moist and protected from the air. The effect was very satisfactory. There was no subsequent smarting and burning of the disease, and the spread of the eruption was more limited than I ever obtained by any other dressing. The bowels were kept free by the hyposulphite of sodium, and the tincture of iron was given. Having obtained better results than by any former

treatment, I shall try the combination next time.

E. CHENERY, M.D.

65 CHANDLER STREET, BOSTON,  
June 18, 1886.

#### HYDRASTINE—A CORRECTION.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In your issue for May 15, 1886, in a foot-note appended to my article on "The Physiological and Therapeutic Action of Hydrastine," I stated that Messrs. Parke, Davis & Co.'s hydrastine, which was used in the experiments on man, therein related, was only about one-sixth the strength of Merck's hydrochlorate of hydrastine, which had been used in the experiments on animals. Comparative experiments just completed, and which were made with Messrs. Parke, Davis & Co.'s hydrastine and hydrochlorate of hydrastine and with that of Merck's hydrochlorate of hydrastine, show that they are of about equal strength. The impression of the inequality between the two different manufactures of hydrastine was principally based on the greater burning and pungency which the Merck's preparation produced both on the tongue and when injected subcutaneously. While it is true that Merck's preparation produces greater irritation than that of Messrs. Parke, Davis & Co.'s hydrastine, it is also true that it produces no more than the hydrochlorate of hydrastine manufactured by the latter, and the lethal dose of both of them is about the same in the frog. This difference between the salt and the alkaloid was found too late for verification by experiment before the issue of the journal which contained the article, and in order to avoid any toxic effects which the Merck's preparation might produce if given in the prescribed dose the note was, and, as it is now found, too hastily inserted.

In justice to Messrs. Parke, Davis & Co. this correction is gladly made by

Sincerely yours,

THOS. J. MAYS, M.D.

June 23, 1886.

#### A PORTABLE TURKISH BATH.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In all cases of deep-seated inflammations, whether of the cranial, thoracic, or abdominal cavities, the indication is to equalize the circulation, and thereby relieve local vascular fulness; the same is true of all congestions, that by enlivening the general

circulation we can lessen or remove the difficulty.

In urgent cases of croup, delirium tremens, and those in which rapid serous effusion is an alarming symptom, such a provision will always be a very great assistance.

The apparatus I employ has the following construction: There is a horizontal tube two inches in diameter and four feet long, and a vertical one two feet long, gradually expanded into a funnel-shaped extremity six inches in diameter at the base, and joined to the horizontal by an elbow, the several parts being put together without solder.

Under this funnel is placed an alcohol lamp burning a wick three-quarters of an inch in diameter; and the funnel is perforated by several openings below the level of the flame to afford air-current. Within the funnel, and just above the lamp, are two cross wires to support a cup holding six ounces of water; the cup having shoulders, so that when inserted between the wires and turned it will be supported above the flame by them. To use the apparatus, insert the extremity of the tube under the bedclothes, placing also a vertical strip of lath, or the like, a foot long near it, to make space for hot air, partially fill the cup with hot water, light the lamp, tuck the clothes close around the patient, and it is ready for operation.

In a recent case I witnessed its effect in the treatment of a patient suffering from general anasarca, where the accumulation was enormous, and the tension so great that the venous circulation of the skin was almost arrested, causing it to look black and crack open. There was pericardial effusion, and also oedema of the lungs so extensive that it seemed almost impossible for the patient to survive many hours.

In this case there was mitral insufficiency and an abundance of albumen in the urine, but no tube-casts; there seemed to be general glandular torpor, and she was given a prescription containing Donovan's solution, fl. ext. squills, and digitalis. Of course this was an aid to the treatment; but the abstraction of water through the skin by means of the apparatus did the most to relieve her. I am very sure.

The cost of this instrument is slight, and any tinsmith can construct it. I consider it of great value as an adjunct in the treatment of many cases, and of sufficient importance to merit a notice in any medical publication.

F. W. PATTERSON, M.D.

MILWAUKEE, WISCONSIN.

*EUCALYPTUS AS A TOPICAL AGENT.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In your journal of May 15 I noticed a short article under the head of "Eucalyptus as a Topical Agent," and beg leave to give my knowledge of some of the uses of that valuable drug to your many readers. You say, "According to the few cases Dr. Williams has mentioned, together with the data already published on this subject in previous issues of the GAZETTE, one is encouraged to believe that it can often be used with advantage locally; that there can be obtained from it all the benefits that are to be had by the employment of the tincture of iodine, solutions of nitrate of silver, salts of iron, etc.; and that it can be made use of when these could not be in consequence of some objectionable features attending their application."

The consideration you have here given eucalyptus is true in every respect, according to my experience, as I have given it many a severe trial during the past three or four years, and I now use it almost altogether in place of tincture of iodine, nitrate of silver, etc., as a topical agent in all hyperæmic conditions of a local nature, no matter where. I combine a good fluid extract with an equal quantity of glycerin, which produces much more satisfactory results than the fluid extract alone, as in the latter form it dries too quickly and is somewhat irritating. To an ulcerated and enlarged tonsil, or inflamed throat, its curative action is very prompt and efficient. Of the above mixture, I apply, or direct to be applied, with the aid of a tongue-depressor and probang, a small quantity twice daily for two or three days, and then *pro re nata* until cured, directing the brush to be washed in alcohol or strong salt water, or it will become hard from the resin in the eucalyptus. As an application in metritis and endometritis, ulceration, or, in fact, any inflamed condition of the uterus, I use the following mixture with almost invariable success, viz.:

R Bismuth. subnit., ℥ss;  
Morph. sulph., gr. xx;  
Ex. eucalyptus, f℥ii;  
Glycerin., ad ℥iii. M.

S.—Shake, and apply with absorbent cotton on a probe.

Upon its application to an inflamed part a sense of warmth is experienced, followed almost immediately by a feeling akin to the expression of "that feels good, and I believe it will help me."

Ten or fifteen drops of the fluid extract dropped in the water-chamber on an inhaler—

something like Dr. Barber's—that generates vapor of muriate of ammonium, and used two or three times daily, is, speaking generally, good treatment in catarrhal affections of the head and throat.

W. B. KETCHUM, M.D.

PALO PINTO, TEXAS.

*HYOSCYAMUS IN SINGULTUS.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Having seen a good deal written on the different preparations of hyoscyamus and their effects on diseases, there is one condition or symptom for which I have never seen the remedy recommended, excepting in one instance where the tincture was used with several other ingredients. This condition is singultus in low forms of disease. About six years ago I was called in consultation in a case of an old gentleman in the last stage of pneumonia, in whom hiccough had set in, and was very frequent and extremely annoying. The attending physician had tried several remedies without success. I thought of hyoscyamus, and proposed it, which was agreed to, and I made several pills, giving them to the other physician. He gave one, and in a short time the hiccough stopped, and did not recur afterwards. He took only the one pill, and commenced improving, and recovered. Some time afterwards I had a case in which singultus occurred, and was extremely annoying. I thought of my first trial with the extract of hyoscyamus, and gave a pill, which was the last also, for the hiccough ceased, and I did not have to repeat the dose. The case recovered. Since then I never dread singultus in those low forms of disease of any kind. I have not tried any other preparation of hyoscyamus but the simple extract, that proving good enough so far. My aim in writing this is that others may test the advantages of this treatment.

Very respectfully, etc.,

J. A. CULLUM, M.D.

*THE TREATMENT OF IVY-POISONING.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I would like to ask through the columns of the THERAPEUTIC GAZETTE for a remedy for the poison of the wild ivy. I have tried the usual remedies—sweet oil and acetate of lead—with very little success.

I shall be glad to hear from any of your subscribers. Respectfully,

L. B. PARSELL, M.D.

CLOSTER, N. Y.

[The editor of the *Journal of Cutaneous and Venereal Diseases* (June, 1886) has had a similar inquiry made to him, and, since his experience in the matter is so extensive, his views must be particularly reliable. We therefore print nearly in full, for the benefit of our correspondent, the advice which he gives on this subject.

Medical literature abounds in recipes which have been from time to time recommended as possessing specific virtues in the treatment of this distressing affection; but, however valuable they may have proven in isolated cases, their claims to infallibility have, unfortunately, not been confirmed when submitted to the test of extended clinical experience. It is well at the outset to recognize the fact that *there is no specific for the cure of dermatitis venenata*. It is to be treated on the same general principles as are indicated in the treatment of other inflammations of the skin directly provoked by external irritating agencies. The inflammation is self-limited, with a tendency to spontaneous recovery, and the principles of rational treatment are to relieve the subjective sensations of burning and itching, to modify the inflammatory action, and to prevent the extension of the eruption.

It is well known that the eruption first develops upon parts brought in direct contact with the leaves of the plant, or exposed to their emanations, as the hands and face. The poisonous principle of the rhus resides in a volatile acid termed *toxicodendric acid*. It is still a moot point whether the extension of the inflammation to other parts of the body is a systemic effect, consecutive to absorption of the poisonous principle, or whether it is due to a direct inoculation of the parts by the nails, as in scratching. The latter view is, Dr. Morrow thinks, the most probable; certainly, clinical experience conclusively proves the auto-inoculability of the eruption.

With a view of circumscribing the spread of the eruption, the patient should be cautioned against bringing the hands in contact with other parts of the body; especially should he be enjoined against handling the genital parts, as the integument of this region is peculiarly susceptible to the irritant action of the rhus. It is a matter of common observation that the genital parts of the male are much more frequently the seat of the eruption than the cor-

responding region in the female, and the explanation is found in the direct transfer of the irritating agent by the fingers in handling the parts during the act of micturition, in dressing, etc.

The treatment of the acute stage of the eruption should be essentially soothing and protective. For this purpose, dusting powders and sedative or mildly astringent lotions should be used.

A lotion which Dr. Morrow is in the habit of employing with good results is the following:

R Sodii hyposulphitis, 3i;  
Glycerinæ, 3ss;  
Aq., ad 3viii. M.

Apply with compresses dipped in the solution and frequently renewed. He has also used a strong solution of the sulphite of sodium with marked benefit. Two years ago, he treated several cases by simply painting the affected surfaces, every two or three hours, with sweet spirits of nitre. It seemed to have a very favorable effect in relieving the cutaneous congestion, besides imparting, as one of the patients expressed it, a "cooling sensation" to the surface. In cases where the continuous application of a lotion is impracticable, freely dusting the surface with an absorbent powder is to be recommended. The following may also be used:

R Pulv. zinci oxidi, 3ii;  
Pulv. bismuthi subnitratiss, 3i;  
Pulv. amyli, 3v. M.

It is important that the affected surface should be kept copiously covered with the powder; an occasional sprinkling does little good. If there is much burning heat present, a little powdered camphor (3ss to the 3i) may be added.

When the more acute eruptive features have begun to subside, a mild, soothing ointment should be employed. For this purpose there is nothing better or more universally applicable than the ordinary benzoated zinc ointment. Another very excellent dressing in this stage of the disease is the Lassar paste:

R Pulv. zinci ox.,  
Pulv. amyli, aa 3ii;  
Vaselini, 3iv. M.

It is not claimed that the plan of treatment outlined above is in any sense specific. The writer has employed it, modified, of course, to meet indications in particular cases, in a large number of cases, with the effect of relieving distressing symptoms, and materially hasten-

ing recovery. The good effects of the same treatment will be found to vary in different patients. There is a great difference in the susceptibility of different individuals to the irritant action of the rhus poison, and the difference in susceptibility is perhaps equally marked in relation to the influence of medication.

Two cases of rhus-poisoning came under Dr. Morrow's observation last summer, both members of the same family; in both, the initial features of the eruption were equally severe, both were submitted to the same treatment; in one case it was promptly effectual, in the other the inflammatory symptoms continued, with scarcely any abatement, for several days.

Should the editor's treatment not fulfil the conditions demanded by our correspondent, he need not be discouraged, especially if he believes that in a multitude of remedies there is safety. It is not possible to here enumerate the entire list of remedies which have been recommended in the treatment of rhus-poisoning, for their name is legion. To give only a few which are claimed to possess a remarkable efficacy in subduing the symptoms: lime-water; alum curd; a saturated solution of bicarbonate of sodium; a strong solution of chlorate of potassium; a solution of sulphate of zinc (℥ss to the pint); a solution of carbolic acid (gr. ii to iv to the ℥i); a weak solution of sulphate of copper; dilute lead-water, etc. Compresses to be wet with these lotions, and applied every hour or two through the day. Dr. White, of Boston, and others, highly praise the efficacy of the ordinary black wash. Dr. Brown, U.S.N., claims that bromine (10 to 20 drops to the ounce of olive-oil or cosmoline) is a specific.

To turn now to the vegetable materia medica: a decoction of white-oak bark; a decoction of the bark or leaves of the elder; an infusion of the sweet fern; the tincture or fluid extract of serpentaria, lobelia, sanguinaria; infusion of the bark of the red sassafras, with sassafras tea, *ad libitum*, internally, have all been highly spoken of. Probably the most efficient of the vegetable remedies is the grindelia robusta, which may be used in the form of the fluid extract, diluted in ten to thirty parts of water.

Dr. Hyde speaks enthusiastically of an ointment made by incorporating a decoction of the inner bark of the American spice-bush (*benzoin odoriferus*) with cold cream. Dr. Edson highly extols the virtues of gelsemium in the treatment of rhus-poisoning (*Medical Record*, vol. xxii. p. 120). His formula is:

R Acidi carbolici, ℥ss;  
Fl. ext. gelsemii, ℥ii;  
Glycerini, ℥ss;  
Aq., ad ℥iv. M.

Cloths to be moistened with this lotion and applied to the affected parts.

This, he claims, with the internal administration of the fluid extract of gelsemium every three hours, effectually relieves the burning and itching, and the eruption speedily disappears.]

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Will you kindly give your opinion in your Notes and Queries, what would be the effect upon the system of the excessive use of butter on bread, say spreading bread at least a quarter of an inch thick with it? I think that doctors disagree on this subject, while I have heard some say that such a habit was not good for the system. I know of one case where the doctor actually requested one of his patients to use it spread on very thickly.

Yours, etc.,

READER.

MAINE, June 22, 1886.

[Every one remembers the famous fable of the satyr who indignantly turned out into the storm the belated traveller because he blew his hands to warm them and his porridge to cool it. This act illustrates very well the subject of our correspondent's letter. The doctor who denied butter to his patient and the doctor who ordered butter for his patient were each probably right. Butter is a fat, and in all scrofulous patients the more fat that can be digested the better. If, however, the digestion of the patient be feeble, withholding of fats may be essential. Further, if a patient have a tendency to obesity, or to fatty degeneration of one of the internal organs, abstinence from the use of butter and other fats might be a necessary part of the treatment. As a fat which is easily digested, good butter is an important remedial agent, one which we think ought to be more used than it is, but the question of its administration or its withholding is one to be settled by the judgment of the practitioner for the individual case. Rancid butter is always bad.—EDS.]

THE AMERICAN RHINOLOGICAL ASSOCIATION will hold its fourth annual meeting at St. Louis, Mo., on the 6th of October next.

*SOME USES OF THE TIN OLEATE.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I used the tin oleate some months ago on my finger-nails, which commenced to split and break soon after I left the army, the result of scurvy, contracted in the military service. I anointed the nails every day with the oleate, and at night applied it on a narrow flannel bandage. In about two months all the nails were *sound and tough*. I applied the oleate to the nails of a young lady friend with like success. It is also a beautiful polish for the nails.

Respectfully,

THOS. H. IRQUHART.

HASTINGS, NEB.

*TARTAR.*

The situations upon which deposits of tartar are found upon the teeth are, in order of frequency, the lingual aspect of the inferior incisors,—that is, opposite the openings of the ducts of the submaxillary and sublingual glands, the buccal surfaces of the upper molars which face the orifices of Steno's duct, next the buccal surface of the lower molars, and sometimes the lingual surface of the molars of both jaws. The deposit is never found upon the lingual aspect of the upper incisors, which are not bathed with saliva, and, moreover, are constantly being swept by the tongue. It is capable of being formed in great abundance, especially when from any cause, such as a carious tooth, one side of the mouth only is used for mastication. Tartar is composed chiefly of earthy phosphates and carbonates, with which is mingled a certain proportion of organic matter, epithelial scales, fatty particles, filiform fungi, vibrios, and monas. The relative proportion of phosphates or carbonates varies very considerably in different analyses, and this is due to the material being taken from different parts of the mouth. Thus, if from the buccal surface of an upper molar, it will be richest in carbonates, like the parotid saliva; whereas, when taken from the back of the lower incisors, it contains an excess of phosphates. Tartar is simply a deposition by precipitation of the salts held in solution in the saliva, which is brought about by its contact with air or mucus. The quantity of tartar varies largely in different subjects, for some salivas contain a small proportion of salts, and therefore the deposit is small; also if the precipitate meets with an acid—such as is so frequently found round the necks of the teeth

and due to fermentation—sufficient to neutralize it, it will be redissolved. Thus the presence or absence of tartar has a clinical significance. If it is very abundant, it indicates an alkaline reaction both of the saliva and of the parts around the teeth, and a consequent immunity from caries; but if allowed to accumulate, it produces gingivitis by simple traumatic irritation. In some very rare cases it is entirely absent, owing to an acid reaction in the mouth, which leads to the most disastrous ravages upon the teeth. Between these two extremes there is every mean. The gingivitis due to tartar varies according to the quantity deposited; in a mild case there will be merely a line of redness along the free border of the gum; in a more severe case the roots of the teeth will be stripped of gum and its place taken by tartar; the gum will be festooned, have a fungating appearance, and bleed at the slightest touch; the teeth will loosen and change their position, owing to the inflammation having extended to the alveolo-dental membrane and the absorption of the alveolus. The treatment consists essentially in a vigorous use of the tooth-brush and the periodical removal of the incrustation. Any tooth-powder or preparation which will remove it must be acid, and therefore very deleterious to the teeth themselves. Mr. Bland Sutton has found accumulations of tartar upon the teeth of monkeys, kangaroos, and lemurs at the gardens of the Zoological Society, where it is an occasional cause of death from septic pneumonia. These deposits are almost invariably found in association with a carious tooth or necrosed bone.—*Lancet*, June 5, 1886.

*TEREBENE.*

Certain authorities on lung and throat disease have recently given prominence to terebene as a remedial agent in the winter cough of old people. It has also been found to be an efficient antiseptic, and has been used to some extent in surgery.

Clinically, it is a hydrocarbon, and to the chemist is of interest as an isomer of turpentine. The pharmacist, in the course of his duty, will have it to dispense, and therefore to a study of its chemical properties he must add a knowledge of its pharmaceutical adaptations.

Terebene is a clear, colorless liquid; has a faint thyme-like odor, and has no effect upon a ray of polarized light. This last characteristic distinguishes it positively from turpen-

tine, and the odor by some is described as resembling much that of fresh pine shavings.

According to MR. J. N. HURTY (*Pharmaceutical Record*, July 1, 1886) terebene can be easily and cheaply made by adding to any convenient quantity of turpentine oil five per centum of its weight of U. S. Pharmacopœial sulphuric acid. The acid must be added slowly, almost drop by drop, the turpentine being contained, preferably, in a glass flask, and must be kept very cool. If the mixture exhibits a tendency to grow so warm as to be uncomfortable to the hand, the addition of the acid must be suspended until the heat is subdued. After all the acid is added, it is best to transfer the mixture to a porcelain capsule, so as to expose thoroughly to the air, which exposure should continue for twelve or eighteen hours. This insures complete chemical change, and permits the subsidence of the tarry product, which immediately forms when the acid is added to the turpentine, and which is not wanted.

After standing for the specified time, the clear liquid is carefully decanted from the tarry substance, transferred to a glass retort, and distilled. The distillation can be effected without a condenser if a retort with a long beak be used, the end of which projects into a well-cooled receiver.

It is essential that a correct thermometer be inserted in the tubulure of the retort. Heat can be applied from an ordinary rose Bunsen burner, the retort being raised just high enough to prevent the flame from striking it. Sometimes it will be found necessary, in cold weather or if, perchance, a draft passes through the laboratory, to surround the gas-flame and retort-bulb with a short piece of stove-pipe, which serves to conserve the heat which otherwise would be dissipated.

Some few drops of distillate will appear at about  $130^{\circ}$  C. At  $150^{\circ}$  C. the distillation will proceed freely, the thermometer gradually rising until  $160^{\circ}$  is reached, where it will stand quite steadily until all of the compounds composing the substance we call terebene have passed over. At the first intimation of a rise beyond  $160^{\circ}$  C., the distillation must be controlled by either lowering the heat or, if the distillate has slackened, discontinuing the operation. The products of this reaction, distilling above  $160^{\circ}$ , are not wanted for medicinal purposes.

The distillate will be more or less milky, owing to the small quantity of water formed in the reaction, which distils over; and, moreover, will be acid because of a little sulphurous

acid. Both of these products can be removed by agitating with a small quantity of freshly-ignited potassium carbonate. Separation of the terebene from the compounds formed is slow, but in a few hours is complete. The imperfect terebene thus obtained must be treated with sulphuric acid exactly as heretofore detailed, then distilled and purified. Indeed, these processes must be repeated until the terebene answers to the following requirements: Clear and colorless, thyme-like odor, boiling at  $160^{\circ}$  C., specific gravity .860, .862 at  $15^{\circ}$  C., optically inactive, mutual in reaction.

This product—allene—is resolvable by repeated fractional distillations into terebene  $C_{10}H_{16}$ , boiling at  $150^{\circ}$ ; cymene  $C_{10}H_{16}$ , boiling at  $175^{\circ}$ . The substance left in the retort is principally colophene  $C_{20}H_{32}$ , boiling at  $318^{\circ}$ .

When it is stated that terebene is an isomer with turpentine, it is meant that they have the same formula, which is  $C_{10}H_{16}$ . The word isomer is from two Greek words, the first meaning equal and the second part. Hence, isomer, of equal part or measure.

*Pharmacy of Terebene.*—Medical authority has fixed the dose of terebene at from 5 to 20 drops, and it is prescribed to be given as a vapor, and also to be exhibited in inhaling apparatus. As much stress is placed upon its topical effect, no pharmaceutical form for administration would be admissible that would interfere with this desired end. Two reasons then exist for excluding the pill form. First, the dose is too large to admit of making pills from it of convenient size, even 5 drops requiring an astonishing quantity of absorptive substance—powdered marshmallow, liquorice-root, elm, and tragacanth, etc.—to take it up. Second, the pill form would prevent, obviously, all local effect.

The lozenge form suggests itself as applicable, and likely to meet all requirements. A lozenge, however, to contain a maximum dose of terebene, 20 drops, must be very large if made simply like the U. S. Pharmacopœial peppermint lozenges. To contain even 5 drops, a lozenge twice the size of those just mentioned is required. This difficulty is caused by the non-absorptive qualities of terebene, it seeming to have no affinity of contact with any pill or lozenge-forming substances. This repellant quality, so far as making into lozenges is concerned, can be overcome by making a heavy emulsion of the terebene, and thus introducing it into the mixture of sugar and powdered tragacanth.

The following formula works perfectly, giving a lozenge of good size, holding the terebene satisfactorily, and possessing a taste far from unpleasant. Take of—

Terebene, ℥iiss;  
Acacia, ℥iii;  
Water, ℥ii;  
Powdered sugar, ℥vi;  
Powdered tragacanth, ℥ii.  
Make 100 lozenges.

With the terebene, acacia, and water make, according to article, an emulsion, which add to the powdered sugar and tragacanth, previously mixed together. Beat into a mass, and make into lozenges. The emulsion form, for administration, meets every requirement save one.

The taste of terebene is pretty generally considered bad, and in emulsion its peculiar pungency most successfully salutes and thrusts itself upon the gustatory nerve. Pharmaceutically, however, the emulsion is a success, the following proportions, if observed, furnishing as fine a representative of that class as can be desired :

Terebene, ℥iv;  
Powdered acacia, ℥iii;  
Water, to make ℥ii;  
Syrup of ginger, ℥i.

First rub thoroughly together the acacia and terebene in a dry mortar, add all at once the water, rubbing rapidly until the crackling sound appears, then add the remaining water and the syrup of ginger. This emulsion is not perfectly white, owing to the syrup of ginger, which is added preferably to simple syrup because of its flavor and pungency, which somewhat mitigate the taste of the terebene.

Oil of peppermint might be added to this emulsion with the effect of almost entirely covering up the terebene taste, but unfortunately there are many who dislike peppermint intensely, and hence it cannot be generally used. Oil of lemon improves this emulsion little, if at all, and hence cannot be recommended.

#### AUSCULTATION OF THE EYEBALL.

M. GENÉ has recently described to the Biological Society of Paris a new method of estimating the tension of the eyeball. This consists in auscultating the organ by means of M. d'Arsonval's telephone. The instrument is applied to the globe, and a sound, such as that of the interrupter of a faradization instrument, made to pass : the differences of degree and intensity of the sound, as per-

ceived by the observer, afford a valuable and accurate means of diagnosis. M. Gené's experiments being as yet somewhat incomplete, he hopes at some future time to lay the subject before the society in greater detail.—*Lancet*, June 5, 1886.

#### RHEUMATISM, GOUT, AND DIABETES.

The Croonian Lectures of the present year are mainly remarkable for the assiduity with which DR. LATHAM has attempted to introduce into general medicine an intricate, though necessary, knowledge of some of the intimate chemical processes which are collectively classified under the physiologist's term of metabolism. Were we able to picture accurately the various stages of the chemical processes occurring in the normal integration and disintegration of protoplasm, we should be possessed of knowledge which it is no exaggeration to say would speedily place within our grasp the secrets of nature. As an attempt to propound some of the most important vital chemical changes, every member of the profession must fully appreciate Dr. Latham's labors. But in the present state of physiological science his arguments can only be considered as more or less probably correct. Our information of the way in which a molecule of protoplasm or even albumen is built up is so vague and uncertain, that we have no solid groundwork whereon to build a superstructure. If, then, physiology is so unsettled, pathology must for all purposes be likewise indefinite. At the outset Dr. Latham appeals in large measure in support of his views to an ingenious analogy—first made, we believe, by Pflüger—between the properties of certain cyanogen compounds and those of living protoplasm. This analogy is very striking, and even if it does not actually represent the truth, it probably gives some idea of the difference between living and dead matter. It is a question of a difference in power, in potentiality. The chemical composition, the mere number of chemical atoms, is the same in urea and ammonium cyanate. Urea, however, represents dead matter, more stable but less energetic than ammonium cyanate, which is the representative of living matter in that it possesses energy with instability. Dr. Latham suggests that albumens are structurally cyan-alcohols combined with a benzene nucleus. The energy of albumens comes from their being cyanogen compounds. He shows how the various amide products of the animal

economy may be built up in the laboratory by various chemical interchanges.

What is rheumatic fever? Clinically it consists in the development of various well-known symptoms. How may these symptoms be excited? We have for many years past been taught to believe that causes acting on the central or peripheral nervous system may give rise to joint changes having a close resemblance to those of subacute rheumatism. Is rheumatism a disease of the nervous system? The experiments of Dr. B. Foster have shown that the introduction of lactic acid into the animal economy may be followed by the production of a certain set of symptoms closely allied in appearance to those of rheumatic fever. Does the lactic acid act on the joint structures and vessels directly or through the intermediation of the nervous system? Dr. Latham adopts neither of these views. The Croonian lecturer believes that the *materies morbi* of rheumatism may induce the arthritic signs by its action on the trophic centres presiding over the nutrition of the joints. Lactic acid is formed in excess, but must be regarded as a companion symptom with the other phenomena of rheumatic fever. Not that the acid itself is harmless; possibly it also induces symptoms on its own account. Dr. Latham fixes on uric acid as the irritant to the central nervous system in rheumatic fever. Where and how is the excess of uric acid formed? In order to follow this problem it is necessary to know that there are such bodies as amido-acids. One of these of most importance in our present connection is amido-acetic acid, glycoll, or glycocine. This acid enters into the formation of many important substances. By heating it and urea together, uric acid can be obtained. Glycocine may be formed in excessive quantities in muscular tissue; combined with cholic acid it forms a salt of bile. The liver, therefore, secretes it thus in combination. Now, there are several other ammonia compounds,—leucine, tyrosine, and taurin,—all of which are probably dealt with by the liver, which most likely converts them into urea. The capacity of the liver in this respect may vary for different ammonia compounds. Imagine that the glycocine is not transformed, or only partially so, whilst the other bodies are acted upon, then we should have urea and glycocine together; a conjunction not difficult to imagine, and which possibly actually occurs with the formation of uric acid. But there is the difficulty; such processes are possible, but have not been proved to occur.

On this view the liver is the great offender; on it the "sluggish" liver of our forefathers receives a new interpretation. There are many ways, however, in which the imperfect metabolism of glycocine may be brought about. Take an ordinary febrile catarrh, in which we may suppose that there is an excessive production of amido-acetic acid (glycocine) in the muscles. It goes to the various glands of the body,—liver, spleen, kidneys. Some of it gets converted into urea, and we hear no more of it. Other portions combine with urea to form uric acid, with more or less disturbance of the nervous system, according as the eliminatory organs are in good working order or not.

The vaso-motor system figures largely in Dr. Latham's attempts to explain feverish colds, rheumatism, etc. The vaso-motor system, as has been said of statistics, can be made to prove anything; any physiologist will grant such a proposition. The lecturer pointed out that muscles and glands have special secretory and vasal nerves; urari paralyzes the former in muscle and atropine in gland. The vessels may be dilated without increasing the secretion or metabolism, but still, as a rule, vaso-dilatation means excessive disintegration or descending metabolism. Taking this as a guide, we can easily follow Dr. Latham through the varying effects of exhaustion, paralysis, and stimulation of the various parts, cutaneous, muscular, and glandular, of the vaso-motor system. In rheumatism the (what Dr. Moxon would call) "Secretary of State for the Vaso-motor Department" is in a condition of exhaustion; it has loosened its reins of government; the local departments therefore run riot; or, in other words, there is excessive disintegration and vascular dilatation; the consequences as regards glycocine and the like we have above considered; at the same time lactic acid is formed in excess. In rheumatism, therefore, we cannot blame the liver; it does its ordinary share of work, but too much is put upon it, hence the uric acid and morbid irritation of the nervous system. But in gout it is another matter; the liver is primarily at fault; its secretory cells are not acting up to normal either from defective innervation or inherent weakness. It is possible that glycocine and urea may be conjugated by the renal tissue, and thus lead to the formation of the slightly soluble ammonium urate, some of which may pass away into the general circulation and be transformed into the sodium salt which is deposited in the joints of gouty subjects.

The far-reaching nature of Dr. Latham's subject is still further witnessed by its inclusion of the kidneys, as well as the liver, nervous system, spleen, and general physiological chemistry. A good deal depends on the kidneys: if they are sound the uric acid is readily eliminated; if not, if there be renal inadequacy, then more of the *materies morbi* circulates widely, and so induces the arthritic and other symptoms of gout and rheumatism. It is easy to picture the action of the poison in the blood on the *locus minoris resistentiæ* of various individuals, or the same individual at different times, with the production of gout at the heart, at the toe, at the stomach, and so forth. The arguments in support of Dr. Latham's views afforded by appropriate treatment of rheumatism, gout, and diabetes, by salicylic and benzoic acids and colchicum, are not the least interesting part of the Croonian Lectures.—*Lancet*, May 15, 1886.

#### THE DETECTION OF ALBUMEN IN URINE.

The clinical importance of albuminuria, and the necessity that exists for its early detection as a guide to the treatment of the morbid conditions which give rise to it, have led to the introduction of numerous methods directed to a demonstration of its presence. For a long time the main reliance of physicians in this connection was placed on nitric acid, but of late years other tests than this have been suggested by different observers, until at length quite a goodly number of reagents have been included under the head of albumen detectors. The Clinical Society of London, appreciating the desirability of arriving at some sort of authoritative decision on the comparative value of the methods now in use, recently appointed a committee to examine into and report upon the subject; and on Friday last Dr. W. M. ORD communicated the results of this committee's labors, which were devoted to consideration of the eight following methods of performing the examination of fluids for albumen, viz.: 1. Dr. Oliver's test papers; 2. Dr. Pavy's pellets of citric acid and ferrocyanide of potassium; 3. Dr. Johnson's picric acid test; 4. Sir William Roberts's acid brine test; 5. The picric acid brine test, being a solution of picric acid saturated with common salt; 6. The potassio-mercuric iodide in solution with citric acid; 7. Nitric acid; 8. Acetic acid and heat.

The test papers invented by Dr. Oliver were all carefully experimented with, and in

respect to those saturated with the potassio-mercuric iodide, the committee report that the most satisfactory results were obtained as regards refinement and delicacy of reaction, they being superior in these respects to nitric acid in whatever manner the latter may be employed. Next in order of comparative value they place the ferrocyanide papers; the tungstate papers third; and of the picric acid papers they speak unfavorably, urging that the amount of the acid required for the purposes of detecting albumen is greater than can be supplied by the papers, unless they be used in inconvenient bulk. Even the potassio-mercuric iodide papers, however, possess the drawback that when employed in the cold they require to be supplemented with citric acid, the same objection also applying to the ferrocyanide slips. But it is pointed out that excess of soluble urates in the examined urine gives rise to a precipitate in the presence of citric acid alone, and this fact necessarily introduces a fallacy which it is important to bear in mind in all cases where the papers in question are used for the testing of cold urine; dilution of the excretion is recommended as a means of avoiding the error, as well as the employment of sufficient citric acid to insure a distinctly acid reaction of the fluid. Of the potassio-mercuric iodide it is added, that it appears to precipitate all albuminous bodies, while the ferrocyanide test does not react with artificial peptones. At a later stage of the report, unqualified praise is given to the mode of testing by *solution* of potassio-mercuric iodide, with addition of acetic acid. This is described as the most delicate of all the plans considered, possessing superiority over Dr. Oliver's papers, and giving, especially when applied after Heller's method, reactions of the utmost possible refinement. Dr. Pavy's ferrocyanide of potassium and citric acid pellets are also favorably spoken of, but the same precautions must be observed with them as have been already mentioned, to guard against fallacies due to the precipitation of soluble urates by the citric acid. Further, care must be taken that a temperature exceeding blood-heat is not reached by the urine during their employment: otherwise the ferrocyanide undergoes decomposition.

The picric acid solution suggested by Dr. Johnson is described as being, when used with the addition of citric or acetic acid, or when excess of the picric acid itself is employed, second only to the solution of potassio-mercuric iodide in its reactions. Owing

to the great diffusibility of the reagent, the committee consider its employment after Heller's method inapplicable,—*i.e.*, by floating it upon the urine to be tested ; and to overcome the difficulty in this connection they devised a special method of experimenting, which is fully described in the report ; and they recommend the addition of strong brine to the picric acid to increase its specific gravity in this connection. They further point out that the urine of persons who are taking quinine yields a precipitate with the acid ; it disappears on boiling, but is again thrown down in the cold as a crystalline powder, which, with chlorine water, gives the characteristic reaction of quinine. Uric acid also is precipitated by picric acid, but the effect of heat in dissolving the cloud sufficiently insures its recognition.

The old nitric acid test is, after all, still regarded as affording results the most trustworthy, and as being liable to fewer fallacies than any other of the methods considered. The difficulty surrounding its use is one mainly of convenience, the want of portability being the one objection to its general acceptance in practice. On this ground, and this alone, can other methods claim superiority. The committee also mention acetic acid in terms of high praise, especially as a means of detecting small quantities of albumen, and speak of it as being, in common with nitric acid, particularly free from fallacies such as necessitate especial caution in the use of other tests in the list ; but while thus describing the accuracy of these older modes of examination, they add that they have found an apparently albuminous precipitate formed in some urines after treatment with potassio-mercuric iodide, which yielded no reaction with nitric acid.

All the methods included in the report receive commendation on special grounds, each being considered to possess advantages peculiar to itself, under certain circumstances ; and the committee declare their conviction that any one who constantly employs either of the tests mentioned will be readily able to decide on the presence or absence of albumen with sufficient accuracy for all clinical purposes. For distinguishing the various forms of proteids they regard the possession of several tests as invaluable, while the additional advantage pertains to Dr. Johnson's picric acid test that it affords evidence of the presence of sugar also, when employed with the addition of caustic potash and boiling. We cannot but think this report will prove a most valuable contribution to the study of clinical methods,

and do much to stimulate renewed inquiry in a direction that will lead to ultimate practical benefit.—*Medical Press*, June 2, 1886.

#### TESTS FOR LANOLIN.

The following tests for lanolin are recommended by Messrs. Jaffé and Darmstaedter (*Schweiz. Wochenschrift*, p. 88, 1886) :

1. Red litmus-paper should not turn blue placed over a flask in which two or three grains of lanolin are heated with 10 c.c. of a thirty per cent. solution of caustic soda. Lanolin should be free from ammonia.

2. Pure lanolin, heated in a capsule with five times its weight of distilled water, when melted, floats to the surface, and remains clear on cooling, whereas impure lanolin becomes spongy.

3. No glycerin should be present in the water in which lanolin has been treated upon being evaporated.

4. When kneaded with water, with exclusion of air, it should take up more than its own weight of water without becoming soapy to the touch, and when triturated in a mortar it should not slip off the pestle or spatula.—*Western Druggist*, June, 1886.

#### DETECTION OF ALUM IN BREAD.

The detection of alum in bread is accomplished as follows : A piece of gelatin (free from alum) is immersed in a cold infusion of the suspected bread for twenty-four hours. The gelatin, upon being washed off with distilled water to which has been added a little of a ten per cent. solution of logwood tincture and ammonium carbonate, should not show a blue coloration if the bread is free from alum.—*Western Druggist*, June, 1886.

#### THE HAIR-ROOTS AS INDICATORS OF BODILY OR MENTAL DISEASE.

DR. J. POHL-PINCUS, of Berlin, has recently, in a *brochure* entitled "Polarized Light as a means of Recognizing Irritable Conditions of the Nerves of the Scalp," announced that by an examination of the hair-roots by polarized light peculiar changes may be observed whenever the patient suffers from physical irritation or mental excitement. This statement is the result of investigations which have now been going on for twenty-five years, and the later observations in the course of the research have uniformly confirmed those made earlier.

The hair-bulbs are divided into three groups, as follows: Group A: If, in healthy conditions of the body and mind, the hairs that fall out daily are examined microscopically by polarized light, the enlarged bulbous end of the root will show a white contour, and a yellowish or brownish-red centre. Group B: In all irritable conditions of moderate grade, all painful conditions of any organ, also in emotional disturbances of moderate grade, without any apparent bodily disease, the bulbous end of the hair-root increases in length and breadth (in proportion to the irritation), the central part appears under polarized light of a violet, blue, or bluish-green color, separated from the white contour by bands of yellow and red. Group C: In higher grades of bodily disease or mental disturbance, the bulb becomes still larger, and the bluish centre changes to green, yellow, or orange. A few hairs of the B and C types are found in normal conditions, especially in those more advanced in life. Dr. Pincus gives thirty-one cases showing the effects of painful disease, but more especially of depressing emotions, upon the appearance of the hair-root. The conclusion to be derived from these researches is that bodily disease or mental excitement causes circulatory disturbances, and in consequence a change in the normal nutrition and pigmentation of the hair. This is only in accordance with previous observation, and the chief merit of Dr. Pincus's plan lies in his obtaining a means by which very slight and temporary changes in tissue-growth can be detected and approximately measured.—*Lancet*, May 1, 1886.

#### A SUBSTITUTE FOR COCA-LEAVES.

According to the *Chemist and Druggist* (May 29, 1886) dodonæa-leaves have been sent into England as a substitute for coca-leaves, the consignor being under the belief that they possess similar properties. Though their conformation presents a remote resemblance to that of the coca-leaf, the varnished surface and the liquorice taste should remove any doubt on this point, and, moreover, the absence of the lateral mark along each side of the midrib, which is so characteristic of coca, together with the mucronate apex, will not mislead the close observer to suppose that they are coca-leaves. Moreover, the leaves, though containing abundance of extractive and mucilaginous matter and a little tannin, do not contain an alkaloid; they probably contain a glucoside, but the quantity of the leaves under examination was too small to

afford satisfactory proof of the indications in this direction.

A correspondent further states that there are three dodonæa plants growing in the Edinburgh Botanic Gardens. One of these came from the tropics, and the others are supposed to have come from New Zealand. The fresh specimen of these shows a longer and narrower leaf than those which are the subject of this note.

#### POISONING BY CHLOROFORM.

The symptoms and post-mortem appearances of poisoning by liquid chloroform were—and apparently still are—but little known, and the evidence given on the subject during the past week has been marked by much unavoidable hesitation and uncertainty. Not only did the want of exact knowledge on the one hand hamper the scientific witnesses, especially those who, in courts of justice, were not altogether at home, but the information that is possessed as to the toxic effects of the drug only goes to show how unreliable a poison it is, and how variable are its effects. One result, at any rate, of the recent trial will have been to call attention to the facility with which drugs can be obtained, the use of which under any circumstances must be illegitimate on the part of any other than a medical man. The utter inadequacy of the law on the subject of the sale of poisons is unfortunately a matter of public notoriety, but the ease with which such potent agents as chloroform are shown to be procurable is nevertheless rather startling. Now that the uses and mode of employment of this drug have become public property, it may not unreasonably be anticipated that the future will furnish further details to supply the present *lapsus* in medico-legal treatises. The difficulty with which its employment could be brought home to the culprit if inhalation only were resorted to cannot but enhance its reputation; and unless special precautions be taken, there may be quite a "run" on this particular lethal weapon, as well for offensive as for defensive purposes. Protection can only really be afforded by an absolute prohibition of the sale of such drugs by druggists, under a penal clause, except to medical men or their recognized representatives. To be effectual the onus must be made to rest to a large extent on the vendor, even where his poverty and not his will consents. At present a few "informal formalities" suffice to cover his responsibility, and he is at liberty to go cheerfully and give his evidence

in a case which would in all probability never have presented itself if the law did not almost connive at his carelessness. There are few quite unmixed evils, and it may be that the late *cause célèbre*, besides affording gratuitous and poignant amusement to a crowd of "women and young girls," may serve to point a moral as well as to adorn a tale, by stimulating the progress of a much-needed reform in the laws anent the sale of poisons.—*Medical Press*, April 21, 1886.

#### EQUIVALENT WEIGHTS.

The following rather good story is related in the *Petit Moniteur de Médecine* for April, 1886:

A doctor, practising in the country, brought a package of powder in bulk to a woman, of which she was to give to her husband 75 grains daily. As she said that she had a pair of scales, but no weights, the physician told her that a one-franc piece (a quarter of a dollar) weighed about the amount which he wished to have given, and that she might therefore give him daily the weight of a franc piece of the powder. Two days afterwards the doctor, to his great astonishment, found his patient dead. The explanation of this mystery was, however, readily reached. It turned out that the woman had no silver piece, and that she thought the equivalent in money, no matter how arranged, would be the proper dose; she therefore, instead of putting the silver coin in the balance, put in twenty-five copper pennies. The result was evident.

#### PHYSIOLOGICAL EFFECTS OF MASSAGE.

DR. F. GOPADZE has published a series of observations undertaken with a view to determine the effect of massage on the transformation of the nitrogenous principles of food. He has investigated the history of the subject, and finds traces of it in a Chinese work 3000 B.C. Dr. Gopadze finds that, though there has been a general tendency among authors to assume that massage increases the assimilative power, no exact observations on the subject have hitherto been published. He therefore obtained the co-operation of four medical students, who for three consecutive weeks became inmates of Professor Manassein's clinic, and lived on certain articles of food,—bread, milk, soup, veal, and roast beef,—the quantities ingested being accurately noted. The nitrogen in all the samples of

food, and in the fæces and urine excreted, was determined by the Kjeldahl-Borodin process. Massage was practised for from twenty to twenty-five minutes once a day two or three hours after food. The operations were commenced by *effleurage*, beginning from the extremities and working towards the centre. This was followed by *massage à friction*, *pétrissage*, *tapotement*, a second *effleurage* of each part concluding the whole. The temperature was subsequently taken, and in some cases sphygmographic tracings. In all four cases the appetite was decidedly increased, not only during the week in which massage had been practised, but after it had been stopped; thus, one of the subjects took an average daily quantity of 24.95 grammes of nitrogen during the first week, 30.97 during the second or week of massage, and 29.57 during the third week. Similarly the amount of nitrogenous transformation was augmented during the continuance of massage in all four cases. The augmentation persisted in two of the cases, but in the other two the transformation was less during the third than during the first week. In Case 1 the nitrogenous transformation was increased three per cent. during the second week, and one per cent. during the third. In Case 2 it was increased one per cent. during the second week, but diminished eleven per cent. during the third. In Case 3 it was increased three per cent. during the second week, but diminished ten per cent. during the third. In Case 4 it was increased four per cent. in the second week, and three per cent. in the third. The quantity of nitrogen assimilated increased in all four cases, independently of the amount of food ingested. During massage two of the subjects gained slightly in weight, the other two losing weight, but during the week following the one in which massage was practised all four gained. The axillary temperature decreased for about half an hour after the operation to an extent varying from  $0.1^{\circ}$  to  $0.5^{\circ}$  C., after which it began to rise, attaining its original figure, or from  $0.1^{\circ}$  to  $0.3^{\circ}$  below it, about an hour after the end of the *stance*. The respirations became more frequent, and were of a deeper character. The effect on the pulse varied with the character of the massage. When this was carried on lightly, the pulse became more frequent; but when the manipulation was more forcible, the pulse became slower. The effects in both cases persisted for an hour or more after the termination of the operation. In conclusion, the author suggests that massage should prove useful in chronic gastro-intestinal catarrh, in

chronic constipation due to an atonic condition of the intestines, also in various cases where there is a lack of tone in the abdominal muscles. He also thinks that the practice of massage should be a subject of instruction not only in the Military Medical Academy of St. Petersburg, but in all the medical faculties of the empire and in the institutions for training "feldshers,"—a semi-educated class of men who act as hospital sergeants, and after retiring from the army are put in charge of village communities where there is no medical man.—*Lancet*, May 22, 1886.

#### DIGESTIVE FERMENTS.

An interesting contribution on the value of extract of malt in wasting diseases, by Dr. MURRELL, has recently appeared. The value of this preparation appears to be satisfactorily established, but he attaches a very great importance to testing the specimens of extract of malt before employing them. Otherwise disappointment may follow the administration of an extract which has not been prepared by suitable means, or with proper care, and which, in consequence, is more or less wanting in the active constituents to which alone extracts of malt owe their efficacy. Dr. Murrell calls attention to the fact that it is desirable to be careful to make all experiments with the same sort of starch, for he found in the course of his observations that starches from different sources varied widely in their susceptibility to the action of malt ferments; hence, unless due care be taken to secure an uniform quality in the starch experimented with, erroneous and unreliable results may be obtained. The best variety for comparative tests, according to Dr. Murrell, is pure Maranta arrowroot, ten grammes of which should be weighed out and mixed with a little cold water. This should then be stirred in ten ounces of boiling water over a gas-burner, and when the mixing is complete, the whole should be cooled down to 40° C., at which temperature it should be maintained during the experiments. This latter point must be rigidly attended to, as a difference of one or two degrees materially influences the result. Then again, in testing for the presence of starch with iodine the solution in the test-tube must be cold, as otherwise the characteristic blue reaction will not be produced. Out of eleven specimens of extract of malt so examined, only two were found to transform all the starch within thirty minutes, while several were absolutely destitute of any diastatic

action whatever. Good preparations do not deteriorate on being kept, but the inferior article is apt to undergo fermentative changes. With this simple and easy method of estimating the value of any given extract of malt, the practitioner is enabled to prescribe it with confidence and the discredit which would result to this class of preparation from the employment of inert extracts may be avoided.—*Medical Press*, April 21, 1886.

#### MAGNESIUM SULPHATE IN RHEUMATISM.

DR. S. B. CHASE calls attention in the *Iowa State Reporter*, April, 1886, to the fact that magnesium sulphate will frequently produce great relief in the treatment of muscular rheumatism. He recommends its being given in doses of 5 to 10 grains three times a day in cold water immediately after eating. In his own case it succeeded in producing an entire relief of pain, after various other remedies had failed.

#### A SIMPLE REMEDY FOR CHRONIC DIARRHŒA.

DR. T. C. SMITH, writing in the *Med. and Surg. Reporter*, June 12, 1886, mentions the fact of his having cured a case of chronic diarrhœa, which had lasted for nearly forty years, by the administration of a saturated solution of salt and cider vinegar, a drachm being taken three or four times a day. He also states that since the first instance where he recommended this homely remedy without supposing that it would actually do any good, he has employed it several times in more or less severe cases of chronic diarrhœa, in which it produced great improvement, and, in some cases, cure. Where relapses followed the suspension of the remedy, its renewed administration was again followed by improvement.

#### DIALYZING DIAPHRAGMS.

A practical subject of much importance in the chemical laboratory is that of the relative permeability of various diaphragms, and the paper by HERR ZOTT in the *Annalen der Phys. und Chem.* will be therefore appreciated. Goldbeater's skin carries off the most useful, homogeneous, and water-tight material as a dialyzer, and is twice as effectual under the same conditions as parchment-paper, which, on the authority of Graham, has hitherto been regarded as the best substance. When the solutions to be dialyzed are of such a nature

as to attack organic membranes, ordinary clay cells must be still employed, though they are sixty times less effectual than goldbeater's skin. It appears also that the rapidity of diffusion is increased by the complete exhaustion of the air contained within the pores of the dialyzer; the rapidity is also dependent more on the increase of volume of the solution than on augmentation of the mass dissolved. After a preliminary exhaustion endosmosis takes place, even in the case of slowly diffusible substances such as colloids. The term "colloid" and "crystalloid" are purely relative; two or more substances present in a solution are more rapidly and completely separated the greater the difference of their diffusion velocity. Separation by dialysis is more rapid the more often the liquid in the outer vessel is removed.—*Lancet*, May 22, 1886.

**SAL ALEMBROTH—SIR JOSEPH LISTER'S  
LATEST ANTISEPTIC.**

It may be news to a great many to learn that LISTER has discarded the use of the spray almost entirely, the only cases he has used it in during the past fifteen months being operations involving the peritoneum. After careful examination and study, he believes that the germicide properties in a solution of  $\frac{1}{10}$  carbolic, thrown by the spray into the air three or four feet, to be *nil*, or nearly so, and the sole benefit derived was due to the irrigation and absolute cleanliness induced. Carbolic acid was superseded by perchloride of mercury; this, when used for dressing, was, from its forming an insoluble albuminate of mercury, irritating, and thus an unsatisfactory dressing. He now uses sal alembroth exclusively in his wards for dressings, and it has so far given very fine results. It is a double mercurial salt formed by the sublimation of a mixture of perchloride of mercury and chloride of ammonium, exceedingly soluble. The salt was known to the alchemists; it has not been used in medicine in modern times. Lister prepares all his dressing now with a  $\frac{1}{100}$  solution of this, gauze cotton-wool, lint, bandages, draw-sheets, and where the wound is covered by the shirt, it is rendered septic by dipping it in the solution and drying before the fire. To make any of these dressings, all that is necessary is to soak them in this solution and dry. It not being volatile does not require to be kept sealed in tin cases. He also colors these dressings with aniline blue  $\frac{1}{1000}$ ; the benefit to be derived from this is that wherever an alkaline dis-

charge comes in contact with the dressing, the blue is removed and turned reddish, enabling you at once to see where the discharge has been, if the quantity was ever so small, and had dried up before the dressing was removed. There is one precaution in using this dressing, and that is this,—the dressing being dry and frequently handled, might have some septic matter from bedclothes, hands, etc., so he always dips it in  $\frac{1}{1000}$  perchloride just before applying it. He is making a sal alembroth protective, which will be surcharged with the antiseptic, so that as a discharge comes through a dressing, it will come in contact with this protective, and can be kept aseptic.—*Pharmaceutical Record*, May 15, 1886.

**HYDRASTIN.**

DR. A. T. SLAVATINSKI, who has published as a graduation dissertation an account of his researches on the pharmacological action of hydrastin, which he gave to a number of pregnant bitches and rabbits, as well as to other animals, finds that when introduced into the blood in doses of not less than a hundred-thousandth of the body-weight, or one centigramme per kilogramme of the body-weight, it acts as a stimulant to the spinal cord and medulla oblongata. In medium doses it paralyzes the vaso-motor centres, thus decreasing the blood-pressure. It acts on the heart first as a stimulant, and afterwards as a depressant of the motor ganglia. No effect seems to be produced on the peripheral branches of the pneumogastric. The augmentation of the cardiac contractions begins from the spinal cord. At first the secretory and convulsive centres are stimulated and afterwards paralyzed. Hydrastin, in doses of from 0.01 to 0.03 grm. per kilogramme of body-weight, was found to act as an ecbolic in pregnancy, and to produce contraction in the fibres of the non-pregnant uterus. At a certain period of pregnancy, which for the human subject is about seven months, the drug in the same small doses (0.01 to 0.03 per kilogramme), if repeated a few times, appears to cause a miscarriage. The author had an opportunity of trying the ecbolic effect of hydrastin on a woman who had a contracted pelvis and in whom it was desirable to bring on the labor somewhat before its proper time. On March 3, which was the commencement of the ninth month of pregnancy, a gramme dose of hydrochlorate of hydrastin was administered hypodermically morning and evening. These injections were repeated the

following day. In the evening the patient noticed that the movements of the foetus were particularly strong. On the forenoon of March 5 a gramme and a half was injected, and subsequently two strong movements were felt. The same evening two grammes were injected. On the forenoon of the 6th two grammes were given, and there followed during the day three strong movements. At night three grammes were injected. On the forenoon of the 7th three grammes were given, and one very violent and prolonged movement was experienced. Two grammes were given in the evening. No further injections were required, as signs of approaching labor manifested themselves. The child was born without complications, but it died the next day. Dr. Slavatinski suggests that if further experiments show that hydrastin may be used without danger to the mother, it may well replace the use of instruments in cases where premature induction of labor is required. He considers that hydrastin and its salts are more reliable than other preparations of the root. With regard to the dose for therapeutic purposes, he puts the maximum daily quantity at 0.3 grm. when given hypodermically, but would give doses of 0.5 grm. internally.—*Lancet*, May 22, 1886.

#### MENTHOL IN URTICARIA AND PRURITUS.

Among the myriad of remedies for these troublesome affections we have no other which affords such complete and instantaneous relief as a solution of menthol. Not only is the itching relieved for the time, but a cure seems to be effected. In pruritus and in eczema, moistening the parts with menthol solution causes an immediate cessation of the pain. The solution should contain from two to ten grains of menthol to the ounce of water.—*Amer. Journ. of Pharmacy*, April, 1886.

#### TREATMENT OF ACUTE RHEUMATISM.

The last number of the *Russkaya Meditsina* contains a communication from Dr. L. GRINEVITSKI, of Rostoff-on-the-Don, who writes that for more than twenty years he has treated acute articular rheumatism with nitrate of potassium, two drachms being given daily in raspberry syrup, and a dose administered every two hours. Together with this internal medication he prescribes an ointment for use morning and evening of the following composition: Olei hyosc., 1 oz.; ung. hydrarg. cinerei, 2 dr.; ext. acon., 1 dr. He has tried all ordi-

nary remedies, and finds that on the whole this plan of treatment is more satisfactory than any other, being especially valuable in those cases where salicylates fail to give relief. Generally the disease is brought to an end in from one to two weeks, according to its severity and the time the treatment was commenced. When commenced at the onset of the attack, and before more than one joint was affected, the others were usually spared altogether.—*Lancet*, May 22, 1886.

#### ACTION OF POTASSIUM CHLORATE ON CHLORAL HYDRATE.

K. SEUBERT calls attention in the *Pharmaceutical Record*, May 15, 1886, to the fact that when 165 grammes of chloral hydrate and 37.43 grammes of potassium chlorate are finely powdered, and exposed to direct sunlight in a flask fitted with a reflux condenser, a reaction soon begins with a great rise of temperature, and the flask must be cooled by immersion in cold water. Chlorine, phosgene gas, carbonic anhydride, and chloroform are given off. In four days the reaction is complete, and a separation of crystals takes place, which may be increased by surrounding the flask with ice. The whole is then filtered, and washed with absolute alcohol. Water is added to the alcoholic solution, which then yields on evaporation very pure hydrogen potassium trichloracetate. A small quantity of perchlorethane is also formed in the reaction.

#### WRIGHTINE AND CONESSINE.

Wrightine is an alkaloid which is obtained from the seeds of the East Indian apocynae *wrightia dysenterica* by digestion of the alcoholic extract with dilute hydrochloric acid, and precipitating by ammonia or sodium carbonate. This alkaloid was first isolated in 1864 by Stenhouse, and has recently been described by Haines and Wamecke as the first natural alkaloid which was free from oxygen. Haines claims priority of discovery of this alkaloid, to which he states that he gave the name of conessine.

The alkaloid forms a voluminous, friable mass of colorless crystals, melting by prolonged heat at 60° or 70°, and forming good crystallizable salts with acids. In the pure state, heated carefully in a retort, they undergo sublimation. The salts are with difficulty soluble in water, readily soluble in ether, alcohol, chloroform, petroleum ether, benzol, amyl alcohol, and bisulphide of carbon.

### THE PRIMORDIAL ALIMENTARY PRIN- CIPLES.\*

By PROFESSOR DUJARDIN-BEAUMETZ, PARIS, FRANCE.

THE subject of alimentary regimen, which I intend to consider to-day, is one of the most important connected with hygienic therapeutics and also one of the most difficult. I shall, then, ask your careful attention and your indulgence in the lengthy and perhaps somewhat dry exposition into which I am about to enter.

\* A lecture on Hygienic Therapeutics delivered in Cochin Hospital. Printed from advance sheets.

To give order and method to this vast chapter of hygienic therapeutics, I propose in successive lectures to take up the following points: first the primordial principles of foods, then the complete foods, then complex foods, and lastly beverages. When once we have reviewed these topics, we will define the bases of the normal alimentary regimen, and then study the consequences of an insufficient, excessive, or exclusive dietary regimen, and the application of dietetics to the treatment of diseases.

A man loses every day a certain quantity of nitrogen, of water, and of salts; these daily losses, which are the result of the different acts of nutrition, must be duly compensated by a sufficient diet, otherwise emaciation, de-

bility, and death ensue. The quantity of nitrogen and of carbon has been carefully estimated, and we know that in the twenty-four hours a man loses by the urine 15.5 grammes of nitrogen, and by the fæcal matters, mucus, and cutaneous exhalations, 5.5 grammes, which represent a total of 20 grammes of nitrogen. As for the carbon, we have the high proportion of 310 grammes, of which 250 are eliminated by the respiration, 45 by the kidneys, and 15 by the exhalations, the excrements, and the mucus. The quantity of water which is removed by the respiration, the perspiration, and the urine varies between 2000 and 3000 grammes per day. Lastly, 30 grammes of saline matters daily are also necessary for nutrition.

#### THE PRIMORDIAL ALIMENTARY PRINCIPLES.

Organic principles.	Azotized principles.	Albuminoid, or proteinaceous principles.	Fibrin. Albumen. Glutin. Casein. Legumin. Chondrine. Osseine. Gelatin. Ichthyocol. Cartilage, etc. Theobromine. Caffeine. Theine. Matheine, etc.
		Gelatinous, or non-proteinaceous substances.	
Inorganic principles.	Non-azotized principles.	Alkaloids.	
		Hydrates of carbon.	Starch. Sugar. Gum. Butter. Fat. Oil.
	Salts.	Neutral fats.	
		Chlorides. Carbonates. Phosphates. Lactates.	Sodium. Lime. Potassium.
	Water.		

We give the name of food to all substances, of whatever origin, which, when introduced into the organism, may serve for nutrition; alimentation is the methodical and rational association of these diverse aliments.

When you take a general survey of the primordial alimentary principles of all the different kinds of food, you find that they may all be divided into two great classes,—the organic and inorganic principles. These two great classes are each subdivided into two groups,—the organic into azotized and non-azotized principles, the inorganic into saline principles and water. Let us examine each of these groups.

The azotized principles comprehend three classes,—the albuminoid substances, properly so called; the gelatinous or non-proteinaceous substances; in a third class are ranged certain alkaloids of vegetal or animal origin

which we find among our aliments. The organic non-azotized principles are subdivided into two groups,—the neutral fats and the hydrates of carbon.

The above table gives you a bird's-eye view of these different primordial alimentary principles.

Let us now pass in review each of these subdivisions.

The albuminoid or proteinaceous substances constitute the basis of azotized foods. These are fibrin, albumen, casein, legumin, etc. They all correspond to a general formula whose atomic notation is not yet fixed, but which, in accordance with the recent labors of Sterry Hunt, Schutzenberger, and Paul Thenard, seems to be that of cellulose, plus ammonia, minus water, as may be represented in the following formula:

Their centesimal composition is represented by the following figures:

Carbon.....	53.5
Hydrogen .....	7.0
Nitrogen.....	15.5
Oxygen.....	22.4
Sulphur.....	1.6

You know that Mûlder considered all these bodies as having for basis a special principle, to which he gave the name of *protein*; hence the designation *proteinaceous*, or *protein* compounds, which chemists have applied to all these substances. To-day this view has been abandoned, and the prevalent opinion, since the brilliant researches of Armand Gautier, has been that the albuminoids, some of which, such as xanthine, may be synthetically produced, all have for their basis, or, if you prefer the term, their *skeleton*, certain hydrocyanic compounds, and that the economy excretes as useless or dangerous various toxic combinations under the form of leucomaines and ptomaines; but there is far from being universal agreement on this subject, and, despite the more recent researches of Hoppe-Seyler, of Bechamps, of Schutzenberger, we are still ignorant of the real composition of albuminoid substances.

All these albuminoid principles, whatever may be their origin, whether we have to do with legumin or casein, or with myosin, undergo a special action on the part of the gastric juice, which, by reason of the ferment pepsin which it contains, transforms them, first into syntonin, then into peptone; each

of these principles, moreover, having, as Heninger has shown, a special peptone, so that we find described a fibrin peptone, a casein peptone, etc.

I need not here trace for you the history of these peptones. You all know the great characteristics which separate albuminoids from peptones,—while the former are coagulable by heat and strong acids, the latter are not. The peptones, moreover, present a special reaction with cupro-potassic and cuprosodic liquors,—they turn them to a reddish violet color. At the same time these peptones keep the characteristic reaction of albuminoid substances,—that is to say, under the influence of Millon's reagent, the nitrous nitrate of mercury, they take on the characteristic orange-red color.

Meissner, who has especially studied this question of the peptones, has divided them, you know, into para-peptones, meta-peptones, and dys-peptones. He has even described the peptones *a*, *b*, *c*.

These are questions of purely chemical order, concerning which physiologists are far from being generally agreed.

This rôle of peptonization is not especially reserved for the gastric juice. The pancreas completes the work of the stomach, with this difference, nevertheless, that while the gastric peptonization always takes place in an acid medium (and we know to-day, thanks to the researches of Richet, that this acid is probably hydrochloric combined with leucin under the form of hydrochlorate of leucin), the pancreatic peptonization, on the contrary, is effected in an alkaline medium.

But this is not all. Peptonization has been known to take place in the vegetal kingdom, and Darwin has given us the description of certain carnivorous plants which peptonize albuminoid substances in the same way as the stomach and pancreas. Wurtz and Bouchut have shown us that the juice of certain plants, like that of "*Carica papaya*," of the fig-tree, etc., possesses the same properties.

As for the precise nature of this phenomenon of peptonization, whether effected by the stomach, the pancreas, or by vegetal juices, we are entirely ignorant. At the same time, there is reason to believe (with Wurtz, Hoppe-Seyler, and Schutzenberger) that peptonization consists especially in the hydration of albuminoid substances.

What rôle do these albuminoid substances play in nutrition? Liebig thought that they were chiefly destined for the reparation of our tissues, and in contradistinction to the

respiratory aliments, which are constituted by the fats and hydrates of carbon, the name of plastic foods was given by him to these albuminoid principles.

Gautier has well shown what there is of purely theoretical in this view, and, according to him, these albuminoids have a much larger and wider rôle in the economy. Some of them may pass directly into the organism, and combine with hæmoglobin to form the blood-globules; others undergo hydration to constitute leucin and tyrosin; the peptones, finally, in contact with oxygen, undergo combustion into carbonic acid, and it may be creatine, xanthine and uric acid, and, if the action of the oxygen is continued, we have the formation of water, lactic acid, and especially urea.

As you see, gentlemen, this old notion of plastic foods and respiratory foods ought to be abandoned, and it seems to be a fact that the albuminoid substances furnish not only elements for the reparation of the tissues but also for respiration.

Such was the old, I might say, classical theory of the transformation of albuminoids. To-day Liebig's theory seems to be abandoned, and it has given place to the cellular theory, which is supported by Hoppe-Seyler, Moritz Traube, Pettenkofer, Voit, and Pfüger. From the time of Lavoisier down to Liebig it was held that oxygen, entering the blood by the lungs, then conveyed by the globules to the recesses of the tissues, effected a combustion with the albuminoid principles, the products of which were then eliminated by the different emunctories of the economy, under the form of urea, if the combustion were complete, and of uric acid if it were incomplete; here oxygen played the principal part.

The new theory assigns to oxygen only a secondary rôle. It is the living cell which modifies these albuminoid principles, acting in the same way as the ferments; and, just as we see the yeast-plant transform sugar into alcohol, the *micrococcus of urea* transform urea into ammonia, the *bacillus subtilis* determine the butyric fermentation, so also the living cell disassociates the different albumens, eliminating some, fixing others, and transforming one kind of albumen, such as the albumen of egg, into the albumen of blood or serine. Then, when once this disassociation is effected, according to the wants of the economy, the oxygen accomplishes its office and burns the disassociated elements.

There have been two hypotheses respecting the cellular theories. According to the one,

which is held by Pflüger, Valentin, and Hoppe-Seyler, this disassociation of albuminoid bodies pertains only to the fixed albumen,—that is, to the serine. Voit, on the other hand, maintains that this disassociation performed by the living cell pertains as well to the absorbed and ingested albumen as to the fixed albumen. Lecorché, who has set forth in a very clear manner all these theories in his remarkable treatise on Gout, adopts Voit's theory.

This cellular theory of nutrition appears confirmed by the recent researches of Pasteur and Gautier. Conceding to the living cell the action of figured ferments, it likens nutrition to a fermentation taking place according to the laws established by Pasteur. It also sets forth in clear light the rôle of the living cell, to which Gautier attributes the property of separating from the albuminoid matters the leucomaines which result from their disassociation. I call your attention to these new facts in order that you may see what a change has taken place during the past few years in our ideas respecting nutrition.

But what it is important to know, and what Pettenkofer has set forth in clear light, is that these albuminoids, or rather the waste products of their combustion, pass out of the system in the urine. Hence it is that when we increase the quantity ingested of these azotized substances, we proportionally increase the quantity of nitrogen in the urine. When we deprive the economy of these azotized principles by restraining their ingestion, the organism itself furnishes the nitrogenized waste elements. The following table from Pettenkofer well shows this :

Alimentation.		Nitrogen of food in grammes.	Inspired oxygen.	N. of urine and excrements.	C. in water re- moved by lungs.
Azotized regimen.	{ First day.....	42.61	850	28.71	273.6
	{ Second day.....	42.59	876	36.14	283.1
Mixed regimen.	{ Rest .....	19.48	831.6	19.47	253.1
	{ Work .....	19 4	980	19.28	329.1
Non-azotized regimen.....		1.29	808	13.43	228
Fasting.	{ Rest .....	0	766.25	12.39	195.4
	{ Work .....	0	807.18	12.36	323.9

It is natural that the idea should have occurred of utilizing peptones in therapeutics, and Sanders was one of the first to render such application practicable. At the time of the International Congress of Medicine, which was held at Amsterdam, I was enabled to observe the manufacture of these peptones, and when I returned to Paris I asked Catillon to undertake the fabrication of similar peptones.

The first attempts were not successful, but since then, as you are well aware, the processes of manufacture have been improved and perfected, and to-day peptones of excel-

lent quality are produced here on a large scale.

The experiments of Haly, of Plotz, and those still more recent of Catillon, have satisfactorily proved that these peptones may suffice for alimentation. For a man, in order to sustain life, there is required a quantity of solid peptone equivalent to one gramme per kilogramme of the weight of the body. In the case of the dog, the quantity is still larger, amounting to three grammes per kilogramme. To this daily ration must of course be added hydrocarbons, such as fat and bread.

These commercial peptones have different properties, according to their mode of fabrication. Some are acid, some are neutral, some are liquid, others are solid. Even their reactions are different, showing how complex is this question of the peptones. In any event, whatever may be the commercial brand which you adopt, it seems to me important to recommend the dry in preference to the liquid peptones.

These peptones have a taste which resembles that of glue, and this taste is often so marked as to render the peptones repulsive to many patients. Peptones more agreeable to the taste, such as those of German origin, have been put in the market; but there is reason to fear that gelatin in considerable proportion enters into their composition. When you give these peptones, whether dry, liquid, or gelatinous, you will do well to dissolve them in a little broth. This is not, however, at present a popular mode of administration. I shall endeavor to show you that

the best stimulant of the peptic secretion of the stomach is meat, and that the peptones, far from favoring the secretion of gastric juice and the stomachal digestion, even retard it.

Hence it is that these preparations are far from fulfilling all the glowing promises which you will see held forth in the various advertising sheets commending their use. On the other hand, they render great service in rectal alimentation.

Since the year 1879 I have in fact shown that the large intestine, incapable of itself of

modifying albuminoid substances, fulfils only the function of absorption, and that, if it is desired to feed a patient by the rectum, peptonized enemata are necessary. These peptonized enemata are then the only injections of an alimentary kind worth employing, and I here repeat for you the formula which I have many times given: To a cup of milk add the four following substances: two or three dessertspoonfuls of liquid peptone, or, what is better, two or three teaspoonfuls of dry peptone, the yolk of one egg, five drops of laudanum, and a pinch (seven or eight grains) of bicarbonate of sodium, if the peptones of which you make use are acid, for, as you know, the contents of the large intestine are neutral or alkaline, but never acid.

The second group of azotized organic substances is constituted by the gelatin compounds. We have in this group osseine, connective tissue, tendons, cartilages, chondrine, etc. All these substances have this common character, that their prolonged boiling gives rise to gelatin. It has been recently maintained that these gelatin compounds are digested and absorbed by the stomach. What is certain is that the digestion of many of them is rapid, while, unfortunately, the greater number are composed of tendinous parts which are not absorbable, and which are found almost in their entirety in the stools.

The nutritive value of these gelatinous substances is extremely feeble, and in demonstration of this I need only remind you of the history, so familiar to you all, of gelatin broth, once so highly vaunted by Darcet. The furore for this kind of pabulum was carried to such an extent that manufactures of gelatin broth were established, and the one in connection with the Hospital St. Louis, during the years from 1829 to 1840, is said to have fed 94,542 persons.

The Commission of the Academy showed that this kind of broth possessed no nutritive property. Schiff has, however, shown that these gelatin soups favor the secretion of gastric juice, and that they belong to the class of peptoginous aliments.

I have but little to say concerning the third group of azotized substances which is constituted by vegetal or animal alkaloids. You know that it comprehends theobromine, caffeine, and organic alkaloids, such as the leucomaines and ptomaines. I shall return to these first-mentioned alkaloids when I come to the subject of beverages, and I shall show you that caffeine and its derivatives must be considered as true foods. What I desire to

remind you of now is the curious resemblance which exists between certain products of the oxidation of albuminoid substances, such as xanthine and caffeine and theobromine, for it is proved that caffeine is only trimethyl xanthine, while theobromine is dimethyl xanthine.

I pass now to the study of the organic non-azotized substances; we have divided them, you remember, into two groups: the hydrates of carbon, which comprehend the starches, sugar, and gum, and the neutral fats, which are constituted by butter, animal fats, and the oils.

It is not until they have been transformed into glucose that the carbohydrates can penetrate the circulation. This transformation is effected at different points of the digestive tube. Since the time that Leuchs, in 1831, first pointed out the saccharifying action of saliva on starch, we know by the experience of Schwann, Sebastien, and Miahle that this transformation is due to a special ferment called ptyalin, or salivary diastase. The gastric juice does not prevent this saccharifying action, as Boutron and Frémy supposed, but it favors it, if we may trust to the experiments of Charles Richet.

In this transformation of amylaceous matters, the saliva, it must be remembered, plays only a secondary rôle, while the pancreatic juice is the principal agent in this transformation, as has been well shown by the researches of Bouchardat and Sandras. The pancreatic juice owes its saccharifying action to a particular ferment to which has been given the name of *amylapsin*, and this action is believed to be completed by the secretion of Brunner's glands, which, according to Claude Bernard, are salivary glands of the intestines.

Cane-sugar, in order to enter the circulation, must be inverted, and this transformation it owes to the intestinal juice. When converted into glucose, the hydrates of carbon pass into the blood, and the presence of this body in that liquid constitutes what we call physiological glycæmia. When the quantity of glucose furnished by the amylaceous and saccharine substances is too large, it is eliminated by the urine, and provokes alimentary glycosuria.

The greater part of the glucose undergoes the action of oxygen, and is rapidly burned into carbonic acid and water. Another part is intercepted by the liver to constitute hepatic glycogen, which in its turn furnishes to the economy the necessary glucose when the food no longer contains it.

May these hydrates of carbon supply fat to

the economy? This is a very important question, especially in its relation to the alimentary regimen of the corpulent. According to Liebig there is no doubt on the subject whatever; the carbo-hydrates do furnish fat directly. Soxhlet is of the same opinion, and the fact is patent that in the fattening of hogs the hydrates of carbon furnish the elements of the fat. Voit does not think that starch and sugar supply fat directly to the tissues, but he maintains that these hydrates of carbon, when they are administered along with albuminoid substances, favor the transformation of these substances into fat. It is in fact known, since the experiments of Hennenberg, that 100 grammes of albumen may thus furnish as much as 52 grammes of fat,—that is to say, more than one-half the weight of the albumen.

For my part, I believe in the possibility of the transformation of glucose into fat. Between the formula of glucose,  $C_6H_{12}O_6$ , and that of glycerin,  $C_3H_8O_3$ , there is a great similarity, and it may be affirmed that glycerin results from the breaking up of glucose with an excess of hydrogen. Do not forget that if the greater part of our cells are aërobiotic,—that is to say, living in contact with oxygen,—there is a certain number, as Gautier has well shown, which are anaërobiotic, and it is probable that it is to the latter that is due this special transformation of hydrates of carbon into fats. Whether we adopt the views of Liebig or those of Voit, the results are always the same,—namely, that the hydrates of carbon favor, whether directly or indirectly, the deposition of fat in the economy.

As for the neutral fats, it is in the state of emulsion, and probably after a partial decomposition, that they penetrate the organism by the lacteals. It is to the pancreas that we owe this transformation of fatty substances, which renders them assimilable. I cannot too much insist on the great importance of the pancreas in our digestive processes; and to one-sided dogmatists, who maintain that man should subject himself to a purely vegetable diet, and to those who defend an exclusively azotized regimen, the reply is that man is omnivorous. He is so by the disposition and conformation of his teeth, and especially by the multiple functions and large development of his pancreas, and there is no animal that in this respect bears so strong a resemblance to man as the hog.

The juice secreted by this gland contains, then, three ferments,—trypsin (Schiff), which peptonizes nitrogenous substances; amylap-

sin, which saccharifies amylaceous substances; and steapsin, which emulsifies and breaks up fatty substances.

Do the fats directly penetrate the economy, or do they undergo a special action which transforms them? Despite the experiments of Lebedeff, who, in giving to famished dogs linseed oil or mutton fat, found in the cellular tissue of these animals fatty bodies analogous to linseed oil or suet, we may affirm that every animal by a mechanism which is unknown to us elaborates a special fat. Mutton fat differs completely from that of beef, and the latter from that of the horse, both by their physical properties (taste, smell, etc.) and their chemical composition. But this is not all; in the same animal the composition of the fatty substance varies according to the parts of the economy from which it is taken. All these facts go to show that fatty substances when introduced into the economy are not deposited unchanged in the cellular tissue, but undergo various transformations, according to the individuals and according to the species.

The fats introduced in the food are burned in part, but as their destruction is slow, they are, according to Ebstein, much less concerned than sugars, starches, and gums in the formation of fat in the economy. Hence, as I shall tell you, when I come to speak of the diet of obesity, Ebstein does not exclude fats from his special anti-fat dietary regimen, and he considers these oleaginous substances as most useful agents in nutrition, especially when a man is obliged to undergo extreme hardship and fatigue. The two hundred and fifty grammes of fat pork which the Emperor of Germany provided every day for each of his soldiers during the campaign of 1870 was a sort of official recognition of the importance of fat in the daily dietary of men destined to undergo severe labors.

These results have been in part confirmed by some recent experiments of Debove and Flamart, who have shown that almost the entirety of the fat ingested is stored up in the economy. According to these experimenters, not only is fat an excellent food, but it lessens also the combustion of azotized elements, and in this respect it may be ranged among the waste-restraining foods.

I come now to the last division of the primordial alimentary principles, and shall take up the inorganic principles, which I have divided into salts and water.

As for the salts, Moleschott has shown that thirty grammes (or an English ounce) of

saline substances are necessary for the daily nutrition of man. The rôle of these salts is of considerable importance; it is owing to them and to the combinations which they form with other nutritive substances that the latter both find entrance into and exit from the economy; they are in fact indispensable factors of nutrition. Among these salts two are especially important,—the chlorides and the phosphates.

The influence of chloride of sodium in nutrition has been studied in reference to the food of animals (zootechnics), and it has been demanded if there be really an advantage in giving to domestic animals common salt? To-day all stock-breeders seem agreed that if the administration of salt enhances the nutritive functions in animals, it does not augment their weight. The increase of the combustions of the economy under the influence of chloride of sodium has, moreover, been demonstrated in man by Voit and Rabuteau. The latter, in adding ten grains of chloride of sodium to his daily rations, has seen the figure of urea rise several tenths of a degree.

To what is this augmentation of the combustions due? Is it the result of the increase of the salt (NaCl) contained in the normal state in the blood? To this question a negative answer must be given, for Lehmann has shown that whatever be the quantity of chloride of sodium administered, the proportion of this salt contained in the blood is always the same, and oscillates between 4.138 and 4.140 per 1000. But the chloride of sodium administered is found almost in its entirety in the urine, and it is probable that it is in stimulating the digestive functions, and especially in augmenting the acidity of the gastric juice, as has been shown by the experiments of Dorogon and others, that chloride of sodium benefits nutrition. At the same time, this augmentation of the acidity of the gastric juice was not observed in a patient who was the subject of a gastric fistula, and Herzen claims to have noticed a constant diminution in this acidity when from 10 to 30 grammes of salt were given with the food.

The question of the use of the phosphates is still more obscure than that of chloride of sodium. If we trust to exclusive views, we should have to consider these phosphates as possessing a considerable rôle in nutrition. Ingested in the state of phosphate of lime, they serve for the nutrition of our bones, according to Alphonse Milne-Edwards. As alkaline phosphates, they constitute one of the most important of the elements of the

liquor sanguinis, according to Joly; and, lastly, these phosphates are said to be useful in repairing the incessant losses of the nervous system.

Zootechnic experiments (experiments pertaining to the feeding of animals) have given little confirmation of these views; and, according to those made in France by Sauson and Chery-Lestage, and in Germany by Heiden, the chemical phosphates, both soluble and insoluble, when added to the daily rations, pass out in their entirety in the urine and fæces, the insoluble phosphates being found in the fæces, and have no action on the nutrition of the animals. It is not so, however, in respect to the phosphates which are contained in plants. The introduction of certain seeds rich in phosphates, such as beans and peas, and even the administration of the hulls of grains in the form of bran, favor the development of bones and the appearance of the teeth.

As for man, the question is far from being solved, and despite the fact that we find these salts in their entirety in the urine and fæces, it is by no means proved that the phosphates have no influence on the nutrition. But if you desire to introduce phosphates into the economy, it is not to the numerous pharmaceutical specialties that you should resort, but to the cereals, and to the parts of the grains which contain these salts in an assimilable form.

As for the chemical phosphates, soluble or insoluble, whatever favorable action on nutrition they may have is due to the part which they perform in promoting the intestinal functions, and to the acid elements which they introduce into the economy.

As for the alkaline bases of these salts,—phosphates, carbonates, lactates, etc.,—they are composed of lime, sodium, and potassium, and each of these bases predominates in a special region of the economy,—lime in the skeleton, sodium in the blood, and potassium in the muscles.

I come now to the part which water plays in nutrition. Our entire organism consists largely of this element, and water is eliminated by the urine, perspiration, and pulmonary exhalation. These daily losses must be made good; hence it is easy to understand that the absolute suppression of liquid in the daily dietary is one of the most cruel of inflictions, as persons testify who are condemned to die of starvation: it is the deprivation of water which causes the most intense suffering.

But physiologists have gone further, and

have claimed that water, besides its rôle in repairing waste, promotes the combustions of the economy by augmenting the production of urea.

Fick, Bischoff, and Genth have defended this view, the latter by experiments performed on himself with great scientific rigor. Genth, after a diet day by day the same, sees the figure of urea increase with the quantity of water ingested, and in such a proportion that, after drinking 1485 grammes of water, he voids 1250 of urine, containing 40 grammes of urea. With the ingestion of 2 litres of water, the quantity of urea rises to 48 grammes; with that of 4 litres, to 53 grammes. Forster, Henneberg, Stohmann, Schmiedeberg, confirm by experiments this disassimilating action of water. In France, Germain Sée adopts also this view, and our colleague and friend, Alfred Robin, by experiments made on himself, arrives at the same results as Genth,—that is to say, that water augments the quantity of urea excreted.

The two subjoined tables well show the action of water in promoting denutrition.

#### EXPERIMENTS OF GENTH.

Regimen.	Solid materials. Grammes.	Urea. Grammes.	Relation of urea to solid materials.
Ordinary regimen....	70.129	43.269	61.6
2 litres of water.....	73.057	48.359	66.1
4 litres of water.....	75.356	53.194	70.5

#### EXPERIMENTS OF ALBERT ROBIN.

Regimen.	Quantity of urine.	Density.	Solid materials. Grammes.	Urea. Grammes.	Relation of urea to solid matters.
Average of five days.....	1200	1023.5	65.75	32.53	49.4
Average with 1250 gr. of water.....	2150	1013	65.33	34.76	53.2

All these conclusions have found in our colleague Debove a resolute opponent. In a first series of experiments, he showed that in hypnotized hysterical patients, as long as the diet remains the same, the quantity of water ingested in no respect influences the figure of urea. But to objections which were presented by reason of the subjects of experimentation which he had chosen, it being notorious that hysterical persons offer the most strange perversions of nutrition, he repeated his experiments with his laboratory chief, Flanant.

These experiments went to show that the only modifier of urea is the quantity of food ingested, and that water plays no part in this elimination, although in his experiments he varied the quantity of water introduced from 1 to 4 litres. At the same time he recognized the fact that every time that the quantity of water falls below a certain minimum—*i.e.*,

1 litre—the individual loses flesh, and the figure of urea diminishes.

Despite the rigor with which the experiments of Debove have been conducted, I persist in believing that the rôle of water in nutrition is one of real importance, especially when the water is taken with the food, and I base myself on the laboratory experiments of Schiff and Vigier rather than on the contradictory results of Robin and Debove.

The first of these experimenters begins by determining the digestive power of an animal. He takes a dog during the period of digestion, kills it, and removes the stomach, which he cuts up in little pieces and infuses in 500 grammes of acidulated water; then he estimates the quantity of albumen which these 500 grammes of water can digest. This varies on an average between 70 and 75 grammes. But if the quantity of water be augmented, and in considerable proportion,—that is to say, by adding 200 litres more,—it is no longer 75 grammes which are ingested, but 75 kilogrammes.

Vigier, in some experiments absolutely different, has arrived at the same results. If you place in four separate flasks 60 grammes of water, acidulated by 1 per 1000 of hydrochloric acid, 50 grammes of pepsin and 10 grammes of fibrin, and if to three of these you add variable proportions of peptones, and do

not make this addition to the fourth, you will see that it is in the latter only that digestion is completed at the end of six hours, while in the three others it is retarded exactly in proportion to the quantity of peptones which you add.

During our meals, when we ingest a certain quantity of water, we facilitate the passage into the rest of the digestive tube of the peptones constantly formed in the stomach, and in this way we favor the action of the gastric juice on the food ingested.

Hence, then, while recognizing that water does not act by promoting disassimilation, it is plain that it is indispensable to nutrition, and that it favors in a certain measure the digestive function. I shall, however, have more to say on this subject when I come to the hygiene of drinks, and the influence which the abundance or suppression of these beverages has in the treatment of diseases of the stomach and in obesity. I am now done with the pri-

mordial alimentary principles, and intend in the next lecture to treat of complete aliments.

### THE PATHOLOGY AND TREATMENT OF DROPSY.

By JAMES BARR, M.D.

*Read at the Liverpool Medical Institution, April 15, 1886.*

(Concluded from page 442.)

**TREATMENT.**—This paper has already assumed such lengthy proportions that I cannot do more now than deal with the general principles of treatment, leaving the consideration of details to some future occasion. As in every other disease, our first object should be to remove the cause, or, as far as possible, remove the conditions on which the dropsy depends. If the fluid be poured out in consequence of inflammation, then there is very little hope of successfully treating the dropsy until you have allayed its cause. You may no doubt, in many instances, remove the fluid by mechanical means, but if the inflammation continues fresh fluid is soon poured out, and this in many cases takes place very rapidly, because the mechanical removal of the fluid diminishes the pressure on the external walls of the capillaries, and so relatively increases the tension within. Pleural and pericardial effusions afford about the only instances where it may become imperative to remove the fluid during the progress of the inflammation. Every one must have noticed the rapid re-accumulation of fluid which frequently follows the tapping of the pleura under such circumstances. The pleural tension is never great, and is frequently negative, so that in many cases you cannot remove any fluid except by means of the aspirator or a siphon. It might be thought that the removal of a negative pressure could not much disturb the balance of pressure within and without the capillaries, nor lead to further transudation. It must be remembered, however, that in health the pleural cavity is abolished by the atmospheric pressure keeping the lungs distended against the parietes. The elasticity of the lung is opposed to this distention, so when effusion takes place it merely compresses the yielding lung. The fluid and inflammatory processes compress and bind down the lung, thus rendering its expansion difficult, and so when the fluid is removed the negative pressure within the pleura is great. The atmospheric pressure counteracts

this tendency to a vacuum by expanding both lungs as much as possible, contracting the chest-walls, raising the diaphragm, and causing a rush of blood into the lax vessels, which readily leads to renewed transudation. If the chest-walls be very rigid, you may get congestion of both lungs and bronchial œdema. This leads us up to the question as to what cases are suitable for operative interference, but however tempting the subject we cannot here approach it. After tapping the pleura I am in the habit of giving, with the best results, small and frequently repeated doses of aconite, with the view of quieting the circulation and diminishing the pressure in the pleural capillaries.

In local œdemas due to vaso-motor paralysis, posture is a most important point in treatment. We should as far as possible avoid the effects of hydrostatic pressure in distending the dilated vessels. In cases of fractures of the leg it is no uncommon circumstance to see the patient kept in a horizontal position for five or six weeks with the limb tightly bandaged, and the blood-vessels more or less damaged both from the effects of the injury and compression in the course of treatment. Immediately on removal of the splints the patient is allowed to place the limb on the ground, and the damaged vessels are dilated with the weight of the blood-column and force of the heart. It is not therefore surprising that surgeons have considerable experience in œdema of the lower extremities. The more rational treatment would be to keep the limb elevated for a week or two, and use passive motion and *effleurage* until the vessels have recovered their tone.

The dropsy of anæmia generally consists of œdema about the feet and ankles, though I have seen general anasarca without any other apparent cause. Although there is usually rather high tension, the blood-vessels are dilated, and the heart is unable to cope with its extra work. Treatment in the recumbent posture is very desirable, as it lessens the work of the heart and removes the effect of gravity on the lower extremities. Cardiac and vascular tonics are here demanded.

The different preparations of iron and arsenic are often advantageously combined with digitalis, though in the use of the latter drug some care is frequently required. It strengthens the heart's action, but it also increases the work it has to perform by contracting the arterioles, and this may be more than a feeble heart is able to accomplish. Hence, in many cases I often find it useful to

counteract its effect on the periphery by small doses of nitro-glycerin.

In the dropsy attending acute Bright's disease, there is defective elimination of water with consequent hydræmia; the capillaries are overloaded and the velocity of the blood in them diminished. In the early stages it is important to combat the inflammation of the kidneys, and for this purpose local or general blood-letting and antimony are the most effectual agents. The quantity of fluid ingested should be regulated by the state of the emunctories. In this form of dropsy free action of the skin is most important, not so much for removing the dropsy as for relieving the kidneys and getting rid of waste products. The emunctory function of the skin is great, and offers the best substitute for inactive kidneys. With many patients a most essential step towards free action of the skin consists of a warm bath with a liberal allowance of soap. Then the free perspiration is better maintained, and with more comfort to the patient, by hot air, rather than by warm water-baths. In many cases the wet pack is also very effective.

By sweating you can only remove fluid from the circulation in the skin capillaries, and before that which is effused can be thus eliminated it must be absorbed into the blood-vessels.

In some cases, where the anasarca is great, the skin distended, white, and glistening, and the blood thus driven away from the surface, it is most difficult to induce free perspiration, and in these cases you should not hesitate to puncture the limbs either with Southey's trocars or simply with the needle. The dread of producing sloughing by this procedure often deters from its performance until almost every other remedy has failed, and until a time when little more than temporary benefit can accrue from its adoption. In my experience you may advantageously puncture the limbs in the very early stages of the disease. Once the œdema of the cellular tissue is relieved, the blood circulates freely in the surface, and diaphoresis is easily promoted. I may here quote the following paragraphs from my paper on "The Pathology and Treatment of Tubal Nephritis":\*

"Diaphoresis is usually best promoted, and with least depressing effect, by keeping the patient warmly clothed in bed, and giving him a hot-air bath each day, or every other day, as deemed advisable.

"The bowels should be well unloaded, at first with a strong cholagogue purgative, and afterwards there should be at least one free evacuation daily. Opinions differ very much as to the extent to which purgation should be carried. Some, with the idea of relieving the kidneys and removing the dropsy, have the intestines washed out several times a day with strong hydragogue cathartics, such as elaterium and compound jalap powder. It is held that an inflamed organ requires rest, and therefore you must make the skin and bowels do the work of the kidneys, but this idea of rest is frequently carried to the degree of severely depressing the vitality of the patient. I quite agree with Dr. Howship Dickinson† that 'much mischief has probably been done by purging and sweating, though in moderate measure and in due place these means of elimination are not less than invaluable.' 'Hydragogue purgatives and vapor-baths, however necessary when uræmia is pressing, must be used cautiously, as tending to divert the water which is wanted for washing out the uriniferous tubules. The repeated use of hydragogue purgatives should be limited to obstinate and hopeless cases.'

"Our object should be to establish the function of the kidneys as soon as possible, for at the best the skin and bowels are poor substitutes. As long as the inflammatory process is progressing the discharge of urine will be scanty, and there is little use in giving remedies specially intended to increase it. Then we should endeavor to subdue the inflammation, clear the bowels, and promote the action of the skin. When these desirable objects have been attained, and the circulation in the kidneys restored, then we should encourage the free discharge of urine. If the views which we have expressed on the pathology of albuminuria be correct, then the free discharge of urine will lessen the congestion of the kidneys, and thus promote their recovery. As the velocity is increased, the lateral pressure will be diminished in the Malpighian capillaries, and the copious discharge of water will wash away the debris in the tubules. The transudation of water from the Malpighian capillaries is purely a mechanical process, and by diminishing the congestion of the kidneys and clearing out the tubules, it gives true rest to the organs. Dr. Dickinson says, 'Physiological repose is to be sought, not by debarring the glands of the harmless and necessary solvent, but by cutting off the

\* *Liverpool Medico-Chirurgical Journal*, July, 1883.

† *Pathology and Treatment of Albuminuria*, p. 115.

materials of urea and uric acid. Spare diet and "spring water clear" may often be found sufficient though simple remedies. Of all diuretics water is the best.\*

"My revered teacher, Professor Gairdner, strongly advocates the use of mild saline diuretics, especially the bitartrate of potassium. He says,\* 'My own practice being usually to give the compound jalap powder in doses of from 10 to 30 grains every four hours until purgation is established, which is followed up by cream of tartar solid, in electuary, in 20-grain doses; and finally, when diuresis occurs, as often happens in a few hours, it is kept up by the cream of tartar in solution given alone, or with orange or lemon peel (imperial drink) indefinitely, and with the happiest results, etc.' It will be thus seen that Dr. Gairdner differs from Dr. Dickinson in not surcharging the blood-vessels with extra fluid until the action of the kidneys is attained, but then he has no objection to a free allowance of 'spring water clear.'

"I have frequently seen diuretics succeed in removing the dropsy, and with the best results to the patient, when diaphoretics and purgatives failed. About the best diuretics, in these cases, are bitartrate, acetate, citrate, and bicarbonate of potassium; and we may also include the salts of sodium and lithium. These alkaline remedies have not only the advantage of rendering the urine less acid or alkaline, but also increase the elimination of acid from the system. Dr. Beale in his remarks† 'On the Effects of Diuretics and Sudorifics in certain Acute Inflammations,' says, 'The increased secretion of urine, the profuse sweating, often accompanied with increased action of the bowels, which mark the occurrence of resolution of the inflammation,—that is, of the death of the cells or masses of germinal matter which enter largely into the formation of the "inflammatory lymph,"—are undoubtedly encouraged by giving acetates, citrates, carbonates, and some other salts.'

"In obstinate and chronic cases more stimulating diuretics may be used, such as squills, sweet spirits of nitre, broom tops, oil of juniper, etc. When the heart's power is flagging, and the blood requires more motion imparted, then digitalis is the agent required. It may be presented alone, or in combination with other diuretics, or administered hypodermically in the form of digitaline. Some think

highly of digitalis fomentations, but personally I have never been quite convinced of the *rationale* of the treatment, as, especially in those cases of dropsy, the absorptive power of the skin must be very slight, and there cannot be much special action through the nervous system. I prefer giving the digitalis in some of the before-mentioned modes, and applying fomentations to the loins without any anticipations beyond those to be expected from heat and moisture. If there be much anæmia and defective vascular tone, it may be necessary to employ iron in the treatment of the dropsy.

"Benzoate of ammonium is a favorite remedy with me in Bright's disease, especially where there are any uræmic symptoms, in which cases I have seen most beneficial results. It is a cholagogue and diuretic, and can be prescribed with the acetate or citrate of potassium, liq. ammon. acetat., etc. Dr. Garrod has shown‡ that benzoic acid and its compounds are not only discharged in the urine as hippuric acid, but they also convert uric into hippuric acid."

In granular kidney, dropsy does not take place until the late stages, when the heart begins to fail; our treatment should therefore be directed to strengthening this organ and lessening the amount of work which it has to perform.

In the second class of cases of dropsy our efforts should be directed as far as possible to remove the obstruction. When a vein is occluded we should favor collateral circulation, use postural treatment so as to remove the influence of gravity, and thus encourage the return of blood and lessen the supply. Lymphatic obstruction does not usually give much trouble if there be no inflammation. In cases of ascites due to cirrhosis of the liver it cannot be supposed that the obstruction ever disappears; yet many cases are permanently cured, and this is no doubt due to the blood-vessels of the abdominal viscera adapting themselves to altered circumstances, and so contracting their lumen that the blood-supply is no greater than that which can be returned by the portal system. This condition is favored by lessening the amount of fluid taken in, vaso-motor tonics, moderate catharsis, and diuresis.

In removing the obstruction due to heart-disease, we employ cardiac tonics, rest, diuretics, and cathartics, and frequently lessen the supply of fluid so as to diminish the work of the heart, lessen the hydræmic and statical condition of the blood in the capillaries.

‡ Lumleian Lectures, *Brit. Med. Journal*, April 21, 1883.

Where there is obstruction in the lungs, we also use expectorants and emetics.

We have now to consider the various agents which we employ in the treatment of dropsy, and we will first deal with the question of lessening the supply of fluid. This is a very old treatment, but it is one which has, in my opinion, been too much discarded of late years. It is no uncommon thing to see the medical attendant in a case of dropsy determining that the patient is to be sweated, purged, or plied with diuretics, and carrying out his intention with a very vigorous hand, but not paying the slightest attention to the amount of fluid taken in. If you want to empty a reservoir quickly, your attention should not merely be taken up with increasing the outflow, but also to cutting off the rivulet which keeps it full. If the outlet cannot be made greater than the inlet, then your efforts will be futile until you direct your attention to the latter. When the emunctories are acting well, and the heart's action vigorous, then you need pay little heed to the amount of fluid taken in. In fact, in many such cases—as in acute tubal nephritis when the inflammatory mischief has subsided—the best diuretic is an abundant supply of pure water or milk. But where the excretory functions act badly, and especially where there is structural disease of the myocardium, then all heroic treatment should be avoided, and the amount of fluid taken into the body should be carefully regulated. In local dropsies, lessening the supply of fluid ingested can have no beneficial effect; in short, this negative treatment is only of use in the conditions which I have just indicated.

*External Agents.*—I have already referred to posture in the treatment of dropsy due to *vaso-motor* paralysis. This can be beneficially supplemented by friction with or without a rubefacient, and the application of a mild counter-irritant such as iodine. The recumbent posture is very essential in the treatment of most cases of dropsy, especially in that arising from heart-disease. In large, fat, flabby individuals, where the cardiac degeneration is not far advanced, and the eliminating organs fairly healthy, *massage* gently and judiciously applied is often very useful in improving the tone of the tissues and getting rid of part of their superabundant fat. Such persons are usually gourmands, who will not readily believe or admit that their tissue-degeneration has been brought about by their habits. They should be taught merely to eat to live, and that in proportion as they reduce

the size of their paunch they will lessen the work of the heart and prolong life.

Counter-irritation, even to the extent of vesication, is often of great service in chronic effusions from inflammation of the peritoneum or pleuræ. In hydrocephalus it may be tried, but here you must depend more on general treatment. Occasionally you meet with cases, especially in men of middle or more advanced age, with symptoms of rapid cerebral effusion, due to over-fatigue and consequent nerve-exhaustion, without any organic disease. In these cases the prompt application of liquor epispasticus to the nape of the neck, or even over the whole of the shaved scalp, may save the patient from an untimely end.

*Mechanical Removal of the Dropsy.*—The advisability of thus getting rid of effused fluid and the time to operate have long been disputed points. For my own part, I am inclined to steer a middle course, and if anything to err on the side of caution. It should be borne in mind that this is only a palliative means; a removal of the fluid does not remove the cause of the dropsy. A cure may follow the removal, but then there must be no fresh effusion, or at any rate a balance must be established between effusion and absorption. Dr. D. J. Leech offers some very sound advice, in an excellent paper on the "Treatment of Dropsy" in the *British Medical Journal*, October, 1882, on the uselessness of energetic treatment in many cases of dropsy. In advanced heart-disease, with degeneration and loss of elasticity in the tissues, he tersely remarks that "it sometimes happens that we cannot drain the water from the œdematous tissues, even when they are pricked or tapped; much less can we remove it by inciting the kidney, skin, or bowel action. We can, indeed, no more remove fluid from the tissues by these means than we can drain a soaked sponge by a trocar."

In many cases, however, the distress of the patient is so great, that even those who reserve tapping as a *dernier ressort* are obliged to have recourse to this method of relief. In the general anasarca of acute Bright's disease, where the skin is white and glistening and not perspiring freely, I am in favor of early puncturing of the limbs or tapping with Southey's trocars. In the later stages of kidney-disease and in heart-disease, puncturing the limbs affords very little permanent benefit, but it is often urgently demanded for the relief of other organs. In large accumulations of fluid in the pleura, I am in favor of tapping as soon as the inflammatory symp-

toms have subsided, though I avoid doing so when the temperature is high, unless the symptoms be very urgent. After tapping, I try to lessen the inflammatory reaction by the use of aconite. I have at present a patient under my care where I have had reason to regret a departure from this rule. The dyspnoea was getting rather urgent, and I tapped earlier than I am accustomed to do; immediately afterwards the temperature rose very high, he became very prostrate, and for some days was in a critical condition, from congestive pneumonia, though I am happy to say that he is now progressing favorably. On the other hand, if you delay the paracentesis too long, the collapsed lung may be irretrievably damaged. You must take into account not only the saving of the patient's life but also the restoration of the function of the lung. The older the patient and the more rigid the chest-walls the greater caution required in paracentesis, and in such cases I think it always well to draw off only a small portion of the fluid. In pericardial effusion, the urgency of the symptoms must be the guide for operating.

In cirrhosis of the liver early tapping is to be commended, but other treatment should not be neglected. All stimulants should be interdicted, the climate should be bracing, the patient should be enjoined to take active exercise, and *massage* of the abdomen will be found useful. The food should be light, nutritious, and in small quantities, the portal system should be kept comparatively empty, and hence the quantity of fluid should be carefully regulated. This aim should also be attained by moderate purgation and a stimulating diuretic, such as balsam of copaiba. Diaphoretics are worse than useless.

Dr. B. Ward Richardson, in his extremely interesting investigations on injection of the blood-vessels through the cerebro-spinal cavity,\* has shown "that the chief point of exit for gases or fluids in the cerebro-spinal canal is by the veins of the canal into the branches communicating with the inferior cava at its lowest part. The fact has many practical bearings, inasmuch as it leads to the almost certain inference that the cerebro-spinal fluid, which is always being secreted, finds its return current into the venous circulation in a similar manner, and that the cord and brain are thus relieved of pressure from it." He records a case of great ascites, where "the patient was quite unconscious, breathed with deep stertor, and had frequent convulsive

starts and tremors." . . . "We had drawn off about eight pints of fluid, letting it flow through an india-rubber tube into a metal pail by the side of the bed, when, to our intense surprise, our patient raised his head and asked, as if awaking from a dream, 'what it was that was running.'" I have myself seen several instances which would support these views of Dr. Richardson.

The old treatment of hydrocele by tapping and injecting iodine, and thus setting up inflammation, which obliterates the sac, is I think usually adopted. Gynæcologists have taught us that the best treatment for ovarian dropsy is to extirpate both cause and effect. The spaying question has caused a division among them as to whether the same treatment should be generally extended to hydrosalpinx.

*Mechanical Support.*—After tapping the pleura or peritoneum it is well to give as much mechanical support as possible, and lower the negative pressure on the external walls of the blood-vessels, by tightly strapping with strong adhesive plaster. We have already spoken of postural treatment, and this may be supplemented in many cases of œdema of the extremities by the support of a bandage. This, of course, is chiefly of use in dropsies having a local origin. When Dr. Martin brought his elastic bandages prominently before the profession I recollect reading an account of their application in the treatment of dropsy, by a gentleman of a "speculative turn of mind." In a case of cardiac dropsy he drove the œdema, by their use, from the lower extremities to reappear higher up. He innocently (or I had better say ignorantly) regretted the occurrence of ascites, as if it had not been for this untoward event, and the death of the patient, he quite expected to have cured the dropsy.

*Diuretics.*—This subject is so extensive (but all the agents of this class are well known) that we cannot do more than barely mention it here. In estimating the action of any diuretic careful attention should be paid to the amount of fluid imbibed,—e.g., in calculating the diuretic effect of bitartrate of potassium you must also take into account the large quantity of water in which it is usually administered. Of the diuretics which act by raising the general arterial pressure, the best are pure water, digitalis, caffeine, squills, convallaria, alcohol, ammonia, and senega. The last two are specially useful where there is lung-complication. In broom tops I have never had much faith, and my experience of sulphate

\* *The Asclepiad*, January, 1884.

of sparteine and adonidine is as yet too limited to speak with any degree of confidence. As a cardiac tonic, strophanthus has the commendation of the high authority of Professor Fraser, but its scarcity has as yet prevented its general use. These drugs are often advantageously combined with agents which dilate the renal arteries or arterioles generally, such as sweet spirits of nitre, small doses of nitro-glycerin or nitrite of sodium, as thus a larger volume of blood is sent through the kidneys and the arterial tension is prevented from rising so high as to overpower the heart. The saline diuretics are also useful in heart-disease. In hepatic dropsy copaiiba is most useful.

From what I have previously stated, it may be gathered that in kidney-disease I am in favor of bland diuretics, such as pure water, milk, bitartrate, acetate, and citrate of potassium, benzoate of ammonium, etc.

*Diaphoretics* are only of use in dropsy arising from disease of the kidneys, and here they are of more value as eliminators of waste products than for removing the effused fluid. I have already sufficiently referred to their use in this class of disease, but I now wish to offer a word of caution regarding the popular diaphoretic pilocarpine. It is an exceedingly powerful and certain sudorific, but it is one which should be used with great care, owing to its very depressing effects and its tendency to paralyze the respiratory centre and produce congestion of the lungs. The quantity hypodermically administered should rarely exceed one-fifth of a grain every other day. The free manner in which I have seen this drug injected has made me think that frequently the patient's life stands in greater danger from the remedy than the disease. A fatal œdema of the lungs is perhaps occasionally ascribed to the malady, when the pilocarpine should rather be thus credited. Oculists, also, frequently prescribe this drug in detachment of the retina (sub-retinal dropsy), more, I think, because it is at present the fashion to do so than from any good effects that have resulted from its use.

*Purgatives.*—In all forms of dropsy it is well to keep the bowels unloaded, but I am much averse to very active purgation; the good results are frequently more than counterbalanced by the depressing effects which follow, and the fluid removed soon reaccumulates. In renal dropsy, however, their use is often urgently demanded. Dr. Matthew Hay, in his valuable work on the Saline Cathartics, has shown that if the patient abstains from

all fluids for some hours, and then takes a concentrated solution of sulphate of magnesium, there is a most profuse watery discharge from the bowels, which, as a consequence, greatly lessens the dropsy. He ascribes this action of the salt to its stimulating effect in secretion rather than to any osmotic action, and no doubt his proofs are very strong on this point, but still I think that he places too low an endosmotic equivalent on the solution, reckoning rather from the equivalent of a one per cent. than that of a concentrated solution. I am, therefore, of opinion that, although it is a strong stimulant to secretion, it has also a very considerable endosmotic effect. Dr. Hay thinks that this mode of treatment is chiefly valuable in ascites arising from heart-disease, and in this I agree with him, provided there be not advanced degeneration of the cardiac muscle. When the tissues have lost their elasticity and the abdomen is flabby, it is highly probable that the fluid will pass much more rapidly from the blood-vessels into the intestine than from the peritoneum into the abdominal vessels, and thus there may be such a rapid fall of the blood-pressure as to stop a feeble heart. This is more especially apt to occur, as during defecation the patient usually adopts the sitting posture, so the arterial blood-column may not reach the brain, and thus fatal syncope may be the result. I am afraid, if this treatment be adopted as a matter of routine, many patients will end their days in the water-closet rather than in their bed.

There is no royal road to the treatment of dropsy, but a careful consideration of the pathological conditions of each individual case, and a sound application of physiological principles of treatment, with a judicious mixture of common sense, will frequently lead to very happy results.

*Discussion of Dr. Barr's Paper.*—DR. CARTER at that late hour would confine himself almost entirely to a few points of practical interest. He would venture to suggest, however, that if the somewhat dangerous task of systematizing were entered upon,—dangerous because it always tempted more to narrow facts down to suit the system,—a more practically useful subdivision of dropsies than the one adopted by Dr. Barr might be made. He thought they might be classed into inflammatory and mechanical, with a third subdivision where, as in many renal affections, inflammation of one organ led to mechanical obstruction in others. Inflammatory dropsies seemed to tend to cure, while mechanical dropsies for the most part grow worse and worse.

Not unfrequently a mechanical was purposely converted into an inflammatory dropsy with the design of curing it. A hydrocele, for example, was tapped, and its sac injected with some irritant fluid, the first effect being to produce a dropsy greater than before. But this inflammatory fluid, unlike the fluid mechanically poured out, was soon absorbed, and then it was found that the surfaces of the serous membrane had undergone such an organic change as to render further effusion impossible. Something similar must often take place in the pleura. In examining hospital adult patients *post mortem* nothing was commoner than to find pleuritic adhesions. Indeed, it was rare to examine a body without finding them. The original pleurisy must have been attended with *some* fluid, but this becoming absorbed, the surfaces adhered and a cure of the dropsy took place.

Turning now to the purely practical part of the paper, Dr. Carter would have been glad to hear from Dr. Barr some qualification of his general recommendation of the use of iron after such dropsies. He (Dr. Carter), as he had stated elsewhere, was quite certain that the employment, especially of the astringent preparations of iron, such as the tincture of the perchloride, was often carried too far. He had seen the elimination of urine diminished or checked, and headache caused by their administration. Sometimes spontaneous diarrhoea came to the patient's relief, and no permanent injury was done; but he thought that the general recommendation to use these salts should be carefully guarded by a precise statement of the conditions where they were applicable. On another point he was not quite sure that he could agree with what was said rather by one of the authorities quoted by Dr. Barr than by Dr. Barr himself. It was the deprecatory tone in which prolonged sweating was spoken of. The free action of the skin afforded the greatest relief, not only to the kidneys physiologically, but as well to the dropsical tissues; and he felt quite certain that this free action might be kept up, especially in young patients, for weeks together, not merely without injury but with positive advantage. When the time came for the patient to move about, if the upper and lower extremities were supported by the gentle pressure of evenly-applied bandages, no harm ever came of the previous relaxation. One practical suggestion he was inclined to make with regard to the cases where albumen and even blood would keep recurring so soon as the patient was allowed to get up and move

about, and this was as to the general advantage of turpentine. It must be given strictly within the limits of its *astringent* effect, ordinarily not beyond 5 minims for a dose, and would be often found extremely useful in checking the outflow when other remedies failed. But as for the employment of it in irritant doses, or of any other irritant form of diuretic, in renal dropsy, he desired here, as he had done at a meeting of the British Medical Association a few years ago, to raise his voice against the practice. Even his recommendation of the *vin diuretique* would be found, on referring to his book, to be confined to cases where the dropsy and albuminuria resulted from the congestion from cardiac disease. In renal inflammation of an acute or subacute character he believed more strongly than ever, with increasing experience, that the best plan was to promote the action of the skin by the warmth of the simple diaphoretics, and perhaps the hot-air or vapor bath; to supply a simple non-irritating diet; to keep the bowels moderately open, but to let diuretics alone. He could not conclude the desultory remarks that he had made without expressing his sense of the great ability of the paper and his regret that the lateness of the hour practically precluded them from discussing it with the fulness that its importance merited.

DR. E. H. DICKINSON would like to reiterate the praise which Dr. Carter had bestowed on this valuable contribution to the literature of the subject. If he were to pass a word of adverse criticism, it would be that the paper was too long, and he thought it would have been well if Dr. Barr had divided the paper and had only taken up one portion of it to-night, and thus allowed more time for discussion. Dr. Dickinson highly approved of the skim-milk treatment of various forms of renal disease; he had tried it very largely with the best possible results. In renal dropsy you should avoid all irritant diuretics, and use only those of a very mild character. He had had good results from digitalis fomentations applied to the loins; the heat and moisture acted favorably on the kidneys, the flow of urine increased, and the dropsy disappeared. In cardiac dropsy he preferred the fresh infusion of digitalis to any other preparation of that drug.

MR. F. T. PAUL had some years ago taken much interest in the question of renal dropsy. It seemed to him that we scarcely looked correctly at the nature of disease. There is a suppression of the renal function in acute

Bright's disease, with retention of the effete materials in the blood, which thus passed out of the circulation into the cellular tissue, and so saved the patient from their poisonous effects. It seemed as if the patient passed his water into his cellular tissue. As the function of the kidneys was restored, the excrementitious products were got rid of, and the dropsy disappeared. The reasons why there was so little dropsy in cases of granular kidney are that the function of the kidney is not suppressed, and there is no great retention of urea in the system. The diet should be light, and as free from nitrogen as possible.

DR. ARCHER remarked on the value and interest of the paper, but at the same time thought that Dr. Barr attached too much importance to the mechanical or hydrostatical causation of dropsy. The condition of the tissues conducing to dropsy did not receive that attention that it ought to. It was laid down as a general principle that inelasticity of the arteries favored transudation; this is doubtless the case, but Dr. Archer asked the reader of the paper how he explained the fact that in the case of a small contracted kidney (the arterio-capillary fibrosis of Gull and Sutton) we rarely had dropsy to any extent, although the vessels were usually rigid to a considerable degree. He also thought the reader of the paper attached undue importance to obstruction in the arterioles and capillaries, and regarded the lymphatics as taking but very little if any part in the pathological process. Pleural and pericardial effusions were instanced as conditions in which the lymphatics were likely to be as much at fault as the minute blood-vessels. Dr. Archer mentioned the different characters of the fluid found in simple pleural effusion. In some cases the fluid withdrawn coagulated spontaneously, and in these, older writers, from close clinical observation, were led to the conclusion that the fluid was not likely to reaccumulate to any large extent. This had been occasionally verified by the speaker. It was suggested that possibly this difference in the character of the fluid might be explained by the lymphatics being primarily affected in one case, the blood-vessels in another. With respect to treatment, the speaker confined his remarks mainly to the dropsy of post-scarlatinal nephritis, as being that of which he had most experience. Generally speaking, he condemned the use of diuretics, especially the more irritating ones. In these cases the occurrence of dropsy should be anticipated and prevented by milk diet, rest in bed, and vapor-

baths. The medicinal treatment in these cases was *nil*.

MR. PRESIDENT AND GENTLEMEN,—I have now to thank you very sincerely for the patient hearing which you have accorded to my long and, I am afraid, wearisome paper. I have also specially to thank my friends, Dr. Carter, Dr. Dickinson, Mr. Paul, and Dr. Archer for their kind criticism.

Dr. Carter rather takes exception to my classification of dropsies, but I think his division into inflammatory and mechanical is more objectionable. I had such a division before my mind when drawing up my paper, but could not entertain it, as, from a physical point of view, it is quite untenable. Inflammatory dropsies are also mechanical, and even Dr. Carter is obliged to admit a subdivision, "when, as in many renal affections, inflammation of one organ led to mechanical obstruction in others." Dr. Carter thinks a strong point in favor of such a classification is that inflammatory dropsies tend to cure, while mechanical, as a rule, grow worse and worse. While many cases of dropsy are incurable, and it would be well if the physician would always recognize the limits of his power rather than attempting the impossible, yet I will not admit that any class of dropsy is incurable, so you cannot have a classification into curable and incurable. Many cases of dry pleurisy which end in adhesions scarcely merit the name of dropsy.

Dr. Carter thinks that I should have expanded my views on the use of iron in acute dropsies, but if I had entered minutely into all the details of treatment I am afraid this lengthy paper would have assumed ten times its present proportions. However, if Dr. Carter will do me the honor of reading my paper on the "Pathology and Treatment of Tubal Nephritis,"\* he will find the following statement:

"To lessen the anæmia which always exists in these cases, iron in one form or other is essential, but the tendency is to give it in too large doses. The quantity of iron which can be assimilated at any time is small, so any excessive amount only passes off by the bowels, and most likely disturbs the digestive organs, which in these cases are very readily upset. Iron should not be given when the tongue is dirty and the hepatic functions disordered, as it will likely aggravate these dyspeptic troubles, greatly increase the arterial tension,

\* *Liverpool Medico-Chirurgical Journal*, July, 1883.

and thus augment the evils it was intended to remedy. When giving iron it may be combined with a purgative, but at any rate the bowels should always be kept freely open. The tinct. ferri perchlor. in 5-minim doses is a valuable remedy, and it may be advantageously combined with ammon. chlorid., magnes. sulphat., etc. Iron in combination with the vegetable acids, in form of citrate, acetate, and tartrate, may be prescribed with the salts of potassium, tinct. digitalis, etc., especially where any diuretic effect is required. The citrate of iron and quinine with digitalis and nux vomica often proves very efficacious, and no doubt many other combinations will suggest themselves to different observers under varying conditions."

Few have more strongly inveighed against the abuse of iron, and even in cardiac dropsy I have seen a patient who had been plied with digitalis and iron *ad nauseam*, rapidly cured with acetate of potassium and sweet spirits of nitre.

Dr. Carter scarcely does Dr. Howship Dickinson and myself justice on the question of sweating. We are both much in favor of it in renal dropsy, the only class of dropsy in which it is useful. It is its abuse we condemn. I am pleased to think that there is not much difference of opinion between Dr. Carter and myself.

My friend Dr. Dickinson and I are agreed on the main points in discussion, unless it be that he is more chary about the use of diuretics.

I cannot quite agree with Mr. Paul about renal dropsy being merely an effort of nature to get rid of excrementitious products. Unfortunately for his theory, the effusion does not always contain a large proportion of urea. In short, his theory is unlike the cellular tissue, "it won't hold water."

Dr. Archer thinks that I do not attach sufficient importance to the condition of the tissues and the action of the lymphatics in the production of dropsy, but he does not tell us to how much importance he considers them entitled. By merely asserting his opinion, without any argument or proof, he places himself outside the pale of legitimate criticism. I am sure he cannot expect me to alter my views on a subject to which I have devoted some thought, merely on his *ipse dixit*. I am always open to conviction, and if he will bring forward some evidence to prove that I am wrong, I shall have much pleasure in changing my opinions. I would have been very pleased to have expressed the relative

effects of the different causes in the production of dropsy in an algebraical formula if they admitted of such exactitude, but, unfortunately, the agents are very varying in their effects, and, as we have no constant to guide us, I have no wish to attempt any impossible definition. Regarding the effects of contracted kidney, I think I have sufficiently explained those in the paper. As to the use of milk, I think it is more frequently given for the disease than its dropsical effects. I am inclined to believe that when my friend Dr. Archer peruses the printed paper, he will find that those little defects which he thinks he has discerned are non-existent.

#### RECOLLECTIONS AFTER ETHER-INHALATION—PSYCHICAL AND PHYSIOLOGICAL.

BY GEO. E. SHOEMAKER, M.D., PHILADELPHIA.

THE following was written in substance within four hours of the administration of an anæsthetic for a surgical operation within the nose. It is intended merely as a record of a rather unusual experience, made with every attempt to give an unprejudiced statement of facts and impressions as they were presented at that time to the writer, without after-coloring. Lest the question of the unconscious influence of previously formed conceptions should arise, it may be stated that he had never before been anæsthetized, that he had not previously heard or read of any analogous experience, and had always supposed that such periods as were not a total mental blank were occupied by distorted visions produced or modified by surroundings, as so often observed in ordinary dreams. It had not occurred to him that there could be any element of reason in the talk of an ether subject, and consequently there was no previous intention to remember or record what he might experience. What this experience might be from a psychical standpoint had not been considered at all, and it was only after inhalation began that the attention was aroused and curiosity excited by a matter of physiological interest.

No dread of either etherization or of the coming operation being present, the inhalation was accepted with a feeling of entire ease and self-control as a mere matter of business. No physical distress was occasioned by it, irritation of the fauces and dyspnoea being entirely absent.

That which could be afterwards remem-

bered with distinctness may be said to have occurred during three periods: (a) of entrance, (b) of unconsciousness,\* and (c) of recovery.

*First.* The period of entrance, which was brief and without excitement, as was afterwards learned.

As the efforts to breathe deeply were continued, the last sentence which could be voluntarily uttered was a rational question in regard to a sheet, which an attendant was directed to spread over me. Then the spreading of the sheet, the touch of the napkin to the face, and the coolness of the ether were distinctly felt; but an effort made immediately to speak a rational sentence failed from refusal of the vocal apparatus to respond to the idea. *I was conscious that I failed from this cause.* What this idea was which could not be spoken could not, unfortunately, be recalled after recovery; though at the time when the idea was formed there was a distinct judgment in favor of its rationality and a reflection on the failure of the vocal mechanism.

These waves maintained their one position, the idea of motion being conveyed by the points which made up the lines, these seeming to run over the elevations at a hurried rate, but with perfect regularity.

There was a constant sound or whirr, not loud, but distinct, as of small wheels or a spindle revolving with great swiftness. This sound-like impression seemed to be connected with the running lines, and ceased as they disappeared. (It may be remarked in passing that the only objective constant sound in the room was made by an Argand gas-burner. The subjective sound did not resemble this, and, moreover, suddenly disappeared.)

These phenomena occupied the whole field. There were present no dreams or visions in

Swiftly running auras or waves seemed to follow one another rapidly from within outward over the limbs, and the "Ego" was gone.

*Second.* The period of unconsciousness, or the wave period.

There was present during this time, and only during this time, the single impression of *two endless parallel lines* in swift longitudinal motion, each line being deflected at a certain point to form a *wave*. There was a uniform misty background, and only a short section of the lines appeared, their total length being unsuggested. They seemed to be made up of points, closely set, so that their longitudinal movement was apparent. The lower line moved from left to right, but the direction of movement of the upper could not be recalled.

The lower line was caught up to the level of the upper so as to form a wave. At a corresponding point a descending wave was formed on the upper line, so that the two waves intersected, thus:

any way connected with human affairs, no ideas or impressions akin to anything in past experience, no emotions, of course, no idea of personality. There was no conception as to what being it was that was regarding the two lines, or that there existed any such thing as a being; the lines and waves were all.

Later came a conception of the relation of those lines to me as an individual, but it was after the first conscious respiration and rational idea to be hereafter described.

After an indefinite time, without variation of the above phenomena, the line in the ascending part of the lower wave grew unsteady, secondary waves being momentarily established on the main curve.

Once or twice the whole lower wave fell

with an instantaneous motion, but it was at once restored.

*Third.* Period of recovery.

Just at this juncture I was conscious of taking a deep inspiration, followed by a profound respiratory pause; the succeeding in-

\* The absurdity of speaking of anything belonging to a period of unconsciousness as being remembered represents only one of the difficulties experienced in trying to express in words that which impressed itself upon a mind, which for the time being was hardly a mind.

spiration being accompanied by the slight sound produced by air passing a lax soft palate when the mouth is open.

With this first conscious inspiration came instantly the first idea or thought of any considerable scope,—namely, that such a respiration during etherization would indicate deep narcosis, near death. There was no fear of death or other emotion; rather a feeling of interest and curiosity as to whether I had been near the edge of life while more deeply under the anæsthetic.

The waves were now lost, very rapidly, but not quite instantaneously, in spite of a strong and determined effort to retain a view of them. I was still unable to speak or move.

Somewhere in this period, probably after the long inspiration, and certainly before the waves disappeared and consciousness fully returned, came a number of curious ideas and impressions, many of which are wholly beyond recall, even the order of those remembered being unknown, except as indicated above. All that can be honestly done is to mention them one after another, with no attempt at sequence.

I was most profoundly impressed that I had been given a glimpse at the simplest expression or essential nature of human existence. It seemed perfectly clear that those lines represented or rather *were* my existence (*i.e.*, as a soul), and that the waves were my human or animal life; or, in other words, that the waves or animal life constituted a temporary modification of a primary condition. The waves were evidently exceedingly delicate, and the slightest disturbing force could apparently cause them to disappear and leave only the two lines. (This idea was strengthened by the flickering of the wave above mentioned.)

The idea obtained that here was a totally new conception to me and to mankind, and that I must remember all that occurred and recount it on completely returning to consciousness.

There was undoubtedly a definite order in which the various phases of consciousness returned, and I determined to grasp and remember the new impressions as they came one by one before me. At first there was no doubt that this could readily be done, all seemed so clear; but as I became more and more able to understand the surroundings in the room, I was less and less able to remember that which I so strongly wished and strove to retain.

There was now a *knowledge* that there was

an influence or power, absolute in authority, felt but not seen, entirely impersonal, separate from me and from humanity. This seemed as evident at that time as does now the existence of material objects around; the mind made no question of it while the effect of the ether was present. In the hands of this power memory stood helpless, controlled by its mighty influence. Firmly, inexorably was my determination swept aside, and I was prevented, in spite of the strongest effort and the most burning desire, from returning to full consciousness with a distinct knowledge of things which to man have always been mysteries.

It is simply desired to record these things as representing the state of the mind at that time; and no attempt is made to account for them, or to suggest that they were the results of the working of other than "natural causes." After full recovery from the ether a strong feeling of awe remained, which wore away gradually after several hours. The strange impressions took a deep hold upon me, and matter-of-fact and unimaginative as I am by nature, it took days to shake off the feeling that I had had a glimpse of another phase of existence; as well as to reason myself out of a new and undefinable dread of ever taking ether again. This last is the more strange since there were none of the common after-effects, such as nausea and vomiting, headache, etc., which would give a physical basis to such a feeling; and since I have always administered ether with the greatest confidence in its safety, when properly used; this confidence enabling me to take it on the day in question with the greatest composure.

On recounting this experience to a medical friend of wide observation and intelligence, it was learned that it was not altogether unique, but that he himself had been much impressed upon taking ether by phenomena which could not be accounted for as the natural workings of the human mind. With the object of recording and studying these phenomena he had again and again submitted to the anæsthetic, with invariable disappointment as regards results; motor paralysis coming on so early as to prevent his writing anything intelligible, and, after recovery, little or nothing being preserved by the memory. Though they were written seemingly in a humorous spirit, the following words of Oliver Wendell Holmes have considerable bearing upon the writer's experience. To quote his own account: \* "I

\* Mechanism of Mind and Morals, p. 46.

once inhaled a pretty full dose of ether with the determination to put on record at the earliest moment of regaining consciousness the thought I should find uppermost in my mind. The mighty music of the triumphal march into nothingness reverberated through my brain, and filled me with a sense of infinite possibilities, which made me an archangel for the moment. The veil of eternity was lifted. The one great truth which underlies all human experience, and is the key to all the mysteries that philosophy has sought in vain to solve, flashed upon me in a sudden revelation. Henceforth all was clear, a few words had lifted my intelligence to the level of the knowledge of the cherubim. As my natural condition returned I remembered my resolution, and staggering to my desk, I wrote in ill-shaped, staggering characters the all-embracing truth still glimmering in my consciousness. The words were (children may smile, the wise will ponder), 'A strong smell of turpentine prevails throughout.'"

Among the thousands who annually are anæsthetized there are few who retain distinctly impressions received while wholly or partly under the narcotic influence. It is not very uncommon for such subjects, however, to be profoundly impressed with the thought that something very wonderful has occurred; and that a systematic effort to record what could be remembered after such experiences would be rewarded by fresh insight into difficult psychological problems is not at all improbable. The conditions for the study are undoubtedly difficult to control. Many cases would be of little value on account of the early involvement of higher cerebral function; and in other instances it would be impossible to entirely exclude the influence of expectant attention, of education, and of temperament; but out of a large number of observations some valuable generalizations ought to be found.

The foregoing account applies to what should have been the regular course of the etherization, in which unconsciousness was not preceded, as has been said, by a period of excitement. Some time during the operation, however,—it could not afterwards be learned just when,—I am said to have so far recovered as to struggle with the greatest violence, and much ether was required to again produce muscular relaxation. Of this period there was at no time the slightest knowledge or recollection, and there were no phenomena remembered which can be associated with it.

Either at the end of this second application

of ether, or, more probably, when apparent unconsciousness first came on, the following physiological conditions were present and the recollection in regard to them was afterwards distinct:

Voluntary motion of the legs, arms, and vocal apparatus was impossible, though attempted.

Muscular sense was present, because the elevation of the chair-back and the dropping of the leg-rest of the physician's office-chair were distinctly felt, as I was seated upright to facilitate the operation. As the trunk rose the forearms dropped helplessly by the sides, with the palms upward, and one of the legs also adjusted itself by gravity.

No visual sensations were produced at the time; but as the eyelids probably remained closed, and there was no power to open them, nothing can be inferred as to the possibility of objective visual sensations.

No auditory sensations from movements of the chair, of clothing, or of persons were produced. No odor or taste was perceived.

Tactile sense was present, as the extensor surfaces of the hands felt the touch of the body on which they rested.

Only a modified general sensibility was preserved, at least in a portion of the distribution of the fifth nerve.

There was a very disagreeable feeling of distention of the left nostril, without actual pain.\* Then an almost unbearable sensation on the same side, apparently produced by a cause operating in the direction of the median line.† This could hardly be called pain, but was worse than pain, and is remembered as the most intensely disagreeable sensation that I have ever had.‡ I would have made any effort to escape this, but was utterly powerless to move. Muscular sense was still present, for under the pressure on the nose the head turned somewhat, and the body slipped lower in the chair. There was not at this time a proper conception of my own or the surgeon's personality. There was, however, at the height of the disagreeable sensation a feeling as though a most atrocious advantage were being taken of my utter helplessness by somebody whom I had before implicitly trusted and considered a friend. The mental effect produced was simply horrible.

How this state of affairs changed, or when

\* Probably produced by the finger of the surgeon being forced deeply into the nose.

† Afterwards verified.

‡ Produced by a chisel-like instrument operating within the nose.

it ceased, is not recalled, but a period of unconsciousness followed.

The interest of this experience is not solely from its psychical peculiarities. To the physiologist it appeals as one recorded instance, if only one, in which voluntary motion was lost, while general, tactile, and muscular sensibility remained in a very considerable degree, and for some length of time, together with at least some higher cerebral function, making it possible to note and remember various modifications of sensation.

It is a common practice with impatient surgeons to begin operations as soon as the muscles relax, but in this case acute suffering was endured after voluntary movement was impossible. While the subsequent production of deep narcosis may serve to obliterate all remembrance of pain from the mind of the patient, the depression following an operation must be increased if a flood of violent sensory impulses be poured upon those centres whose ill-regulated activity or inhibition gives rise to "shock." The gravity of this shock would then differ only slightly in degree from that produced by operation without an anæsthetic.

In degenerations of nerves following disease or injury it is well known that motor fibres lose their irritability before those of sensory function, and that anæsthesia is not always present in peripheral motor paralysis. That ether should first affect the less resistant motor functions would seem probable *a priori*. It is, however, generally held that the functions of the higher cerebral centres are first affected by this agent, then sensory functions, finally the motor.\* This is indeed a matter of common observation, the so-called "stage of excitement," with its emotions, its delirious talk, and its active movements, speaking plainly of the early involvement of the intellectual centres, while co-ordinated muscular movement is still present. At this time stimulation of any sensory area is at once resented by the patient.

That in some instances, at least, general sensibility is lost before motion is shown by Velpeau's† case, in which the patient raised herself up to view a very painful operation,

but afterwards said she supposed she was at the dinner-table.

It is highly probable that no invariable rule can be laid down as to the action of ether on the nervous system of man, in regard to the order of the abolition of function; for certainly in the case here recorded motor paralysis first obtained. Personal idiosyncrasy undoubtedly plays a considerable part, and if we bear in mind the probability that the memory‡ will not afterwards serve, together with the patient's entire want of power to communicate his sensations at the time in the absence of motor control, we may ask with some pertinency whether the received ideas of the time when complete anæsthesia occurs are not wrong in more instances than we think.

The old question here comes up as to the possibility of the testimony of an ether subject having a certain value *in some cases* in regard to what occurred during the period of supposed unconsciousness. More than thirty years ago this question assumed a grave importance in a certain well-known criminal prosecution in this city, and growing out of the discussion, so wide-spread at that time, an exhaustive article was written by Dr. Moreton Stillé on the "Psychical Effects of Ether Inhalation."§ After citing various examples and authorities, the writer thus states the positions which he says may be assumed as correct:

"1st. That the consciousness or perception of external objects and impressions is impaired in the early and lost in the final stage of etherization.

"2d. That during the time the mind remains susceptible to external impressions at all, these reach it in a feeble or perverted manner.

\* \* \* \* \*

"4th. That voluntary muscular movement is not paralyzed until the state of perfect narcosis is produced; at which time, however, all outward consciousness is extinct.

"5th. That the memory of what has passed during the state of etherization is either of events wholly unreal, or of real occurrences perverted from their actual nature.

"6th. That there is reason to believe that the impressions left by the dreams occasioned by ether may remain permanently fixed

\* *Vide* F. E. Anstie, *Stimulants and Narcotics*, 1864, p. 315; Flourens, *Arch. Gén. de Méd.*, 4ème sér., xiii. 434; H. C. Wood, *Therapeutics*, 1882, p. 287.

† *Revue Médicale*, 1847, 101, p. 225. Compare Prof. Pitha's chloroform case. "Si io sento l'incisione, ma non sento dolori." *Vierteljahrsschrift f. d. prak. Heilkunde*, 1848, iii. 155.

‡ Further experiment upon the writer, made through the kindness of Dr. J. P. Crozer Griffith and Dr. Orbison, has been so far completely negative on account of this treacherous action of the anæsthetic on the memory.

§ *Phila. Med. Examiner*, 1854.

in the memory with all the vividness of real events."

These conclusions may be taken to represent the general opinion of the medical profession at the present day, but it will be seen that my own experience was directly opposed to the fourth point.

During the period when the operation was felt, it will be noticed that though consciousness was not perfect, and there was a distorted idea of the animus of the surgeon, it was so far preserved as to make it possible to realize accurately the position of the body and limbs, to feel suffering, and to refer sensations with considerable nicety, even in the nose, where points of stimulation cannot be located as accurately as where tactile sensibility is more highly specialized.

It may also be said that, while going under the anæsthetic, the mind was so clear at the time the vocal apparatus became paralyzed that sensory stimulation of any portion of the body would have been correctly located and afterwards reported. Of this the writer feels certain. Unfortunately, no such stimulation was made at the time.

A single example has little value except as one of many which may be compared one with another. It is with this idea in view that the present record is made. If it serve no other purpose, it may stand as one instance in which correct interpretation was given by the brain to some external phenomena at a time when the idea of personality was absent from the consciousness.

3324 WOODLAND AVE.

#### *ERYTHROXYLON COCA AND ITS ALKALOID, COCAINE.*

BY E. W. HOLMES, M.D., PHILADELPHIA.

IT has rarely happened to see any remedy spring so suddenly into prominence, on so sure a basis, as the alkaloid of erythroxylon coca. This results from its possessing a much-needed function,—local anæsthesia,—from its harmlessness, even in considerable doses, and from its efficacy, being readily tested and demonstrated to the two of our senses best trained,—sight and touch. Too often the question of drug worth depends merely on a more or less certain *belief*, but this is one whose effects can be made evident even to the most doubting.

The shrub from which the alkaloid is obtained is by no means a new discovery. The first European to describe it was Hieronymus

Benzoni, 1542, but the records of its use reach back still farther. In the earlier times the Peruvians regarded the leaves as something sacred, and only the Incas, the priest-rulers, were allowed to have it. They burned it on the altars, held it in the mouth while making sacrifices to the Sun-god, and baskets of leaves were also offered, as otherwise the gods could not be propitiated. The shrub itself came in for a share of their veneration, as it was thought no undertaking would prosper without the benediction of coca.

When the Spaniards invaded the country, they found the leaves passing current as money. Gold, silver, and precious stones were plentiful, but as ornaments only. Among the natives it became common as a masticatory, so that it has long been, and now is, one of the most valuable articles of traffic. It has been estimated some thirty million pounds of leaves are annually consumed, upwards of eight million persons being addicted to its use. The name is derived from *khoka* (pronounced *caca*), the tree,—*i.e.*, this tree above all other trees,—“that heavenly plant which satisfies the hunger, strengthens the weak, and makes men forget their misfortunes” (Stillé and Maisch). In certain districts the natives believe if a dying man can taste a leaf placed on his tongue, it is a sure sign of his future happiness, whilst others put the leaf in the mouth of the dead to insure his passage across the dark river, much as the Greeks placed an obolus under the tongue to pay old Charon.

The reliance on the virtues of the leaf is very great, as it is said to abolish both hunger and thirst, and induce great bodily vigor. One author states he employed a native to do some very laborious work. The man, during five days and five nights, slept only two hours nightly, and did not have any other sustenance than coca-leaves, which he chewed at intervals of two or three hours, and at completion of the contract expressed a willingness to perform the same service again if plenty of coca-leaves were supplied him. In travelling, the guides, to be found in good humor, must daily be allowed three resting spells, when they recline and chew their favorite leaf. Each one carries his *chuspa*, or coca-pouch, containing small round masses of leaves, which have been previously reduced to a pulp by chewing and then dried. Having placed one of these in his mouth, he thrusts into it several times a thin moistened stick which has been dipped in alkali, care being taken not to give pain by contact with the lips. This alkali is carried in a small gourd, and is

obtained from the ash of *chenopodium quinoa* or from calcined oyster-shells. The purpose of the alkali is to add pungency and (un-awares to the Indian) to develop the alkaloid. About two to three ounces of leaves are thus daily consumed, only the juice being swallowed. Although they can thus, with a little parched maize, and sometimes a little boiled potato, travel for days over the dreariest wastes, yet, when *at home*, many of them are not without more generous diet, as they eat the flesh of the llama, flour, and vegetables of various kinds, their principal grain being maize. Dr. Weddell states the Indians chewed coca all day, but at night ate like fasting men, so that it appears, then, not to have clogged the appetite.

The owners of the silver-mines find they can limit the quantity of other supplies, but must allow plenty of coca. Curiously, the men throw their "quids" against the rocks, as they believe the veins are thus rendered easier to work, this being the relic of an old superstition that the deities of the metals presiding over the mines rendered the mountains impenetrable unless they were propitiated by the odor of coca. A native will work twenty to thirty hours continuously, without sleep or rest, and the running messengers have been known to travel seventy miles a day for three days with no other sustenance (Knox, "Boy Travellers in South America," 1885). Not only does it seem to develop the maximum of exertion, with the least fatigue, upon a minimum of nourishment, but it also obviates the dyspnoea consequent upon climbing steep ascents and the attainment of great altitudes. This dyspnoea, called "the puna," is at times of sufficient severity to cause death. In many it occasions headache, vertigo, dimness of vision, with nausea, and sometimes blood flows from the eyes, nose, and lips. One writer (Acosta) thus quaintly relates: "I was seized with so mortal and strange a pang, with straining and vomiting, that I thought to have cast up my heart, for, having vomited up meat, phlegm, and choler, both yellow and green, in the end I cast up blood."

Another traveller states, that after eating a strong infusion of the leaves, he could hunt the whole day, at an elevation of fourteen thousand feet, without feeling more inconvenience than he would have under similar rapid movements on the coast. At the summit of the steepest passes are often seen stone-heaps spotted with masses of chewed leaves, aggregations from the mountaineers, who each has added a stone and his mouthful

of coca as a votive-offering to the deity who has thus far brought him safely o'er his rugged and dangerous pathway.

The shrub grows on the eastern slopes of the Andes, at a level of about five to six thousand feet below the frost limit, where the climate is moist and warm, and rains are frequent and plentiful. The seed is sown in December and January, and the young shoots are transplanted, and tended with great care, the ground being well tilled and watered. In about eighteen months the first crop is gathered, two, three, or even four crops being taken yearly. Each leaf should be picked separately. They are then carefully dried in the sun, and stored in the adjacent store-houses, though in former times they were packed in long narrow baskets, and carried to the plains on the backs of the native *xæos* (sheep). The leaves when fresh are a bright green, an infusion tasting something like a poor quality of green tea. The natives of Peru discard as worthless the leaves after they have been plucked more than five or six months. "Some assays have been reported from Bolivia which seem to show that the leaves when freshly gathered contain a much larger proportion of alkaloid than after transportation to this country" (Lyons, *Am. J. Pharm.*).

There is some difference of opinion as to the ultimate harmfulness of this habit. This much is certain: it is slavery. No one can be induced to break it off. Some say, however, they have never seen any deleterious results further than this, and adduce instances of longevity among its devotees. One of these makes the calculation that a coquero, or coca-chewer, who lived to be one hundred and twenty years old, had consumed about two thousand seven hundred pounds of the leaf in his lifetime.

Others, less enthusiastic in its favor, tell us a confirmed coquero can be recognized at first glance from his unsteady gait, yellowish skin, dim, sunken eyes, encircled with purplish rings, quivering lips, and general apathy. That the coca never causes total mental alienation, but excites the cerebrum and rouses the imagination, so that the subject "revels in pictures of ideal beauty," and the repeated stimulation from its excessive use, after a series of years, wears out the mental vigor and activity. That the system cannot be sustained on coca alone. The coquero is reduced to a skeleton, and may even finally die a victim to his passion.

Evidently long years of contact with the

outside world has not eradicated the craving among the Peruvians, nor has it taken root among other nations, as in the case of tobacco. Possibly it may satisfy some climatic need not felt elsewhere. By certain observers it is thought to act not only as a nerve-stimulant but also as a nutrient, they believing it to contain a component which absolutely takes the place of food.

As long ago as 1853 Wackenroder and Johnson indicated the existence of an active alkaloid, which was first isolated by Gaedeckoe (1855); its physical properties were carefully investigated in 1860 by Niemann, of Goslar, Germany, who gave it the name cocaine. Prof. Schröff, in 1862, mentioned its anæsthetizing power upon the lingual mucous membrane, which was confirmed by Dr. Von Anrep, of St. Petersburg, in 1879. It remained, however, for Dr. Koller, assistant physician at the General Hospital, Vienna, to discern its true value, and to bring it to the notice of the profession in all its practical bearings. Stimulated by the report of Von Anrep, and also by a paper on the same subject by his colleague, Dr. Sigismund Freud, he conceived its use in ophthalmology, and by experiments, first upon rabbits and guinea-pigs, then upon himself, friends, and patients, he gave it its legitimate place in the Pharmacopœia. His paper presented to the Ophthalmological Congress in 1884, I doubt not familiar to the reader, may be summarized, that he shows cocaine hydrochlorate to be a valuable analgesic for painful affections of the eyes, and an effectual anæsthetic in ophthalmic operations, producing conjunctival ischæmia, with dilatation of the pupil. Although his essay had reference only to its use in his own specialty, its more extended applications are only logical deductions from his complete scientific observations and experiments.

Experiments upon the lower animals indicate the effects of the drug are markedly in direct proportion to the amount of the dose, and not cumulative. *In frogs* it is lethal with about 6 grains, and this only after the lapse of twenty-four to thirty-six hours. Upon the heart it is found to act by increasing both its force and frequency, but later on, and in full quantity, the heart becomes irregular, the heart-beat diminished in force and frequency, the number of beats running down to four and six per minute. If a four per cent. solution be applied directly to the heart-muscle, the heart is arrested in diastole. *In mammalia* there is first a stimulation of the nerve-centres, followed by slight enfeeblement. The heart is accelerated and strengthened, the pulse becom-

ing fuller and stronger, excepting in overwhelming doses. The inhibitory nerves of the heart are readily paralyzed by medium doses (Turnbull). Blood-pressure is increased by stimulation of the vaso-motor centres and cardio-motor apparatus (Turnbull), and also by peripheric action on the capillaries, probably by stimulating the terminal endings of the sympathetic.

It paralyzes the sensory nerves by direct action on the terminal filaments, and later on abolishes reflex action by like effect on the posterior columns of the cord. If injected directly upon a nerve-trunk (and this is well worthy of careful notice), it paralyzes its whole distal distribution. It stimulates the respiratory centres, but death is due to asphyxia, the heart continuing to beat after breathing has ceased. The peristaltic movements of the intestine are increased, thus acting as a mild aperient. It has no appreciable effect upon the voluntary muscle, but its action on unstriated muscular fibres is as yet undetermined.

Bosworth has noticed that the drug causes a very notable contraction of the nasal corpora cavernosa, "the local application over the whole membrane covering the lower and middle turbinated bones causing these sinuses to become so rigidly contracted that all the blood which they may have contained is absolutely expelled, and the membrane clings closely to the bony structures, which then become visible in absolute outline." This he has confirmed by repeated observation, and has concluded cocaine "produces rigid contraction in unstriped muscular fibres." If this is so, the contraction of the capillaries, as well as the sinuses, may be due to direct action on their muscular coats, a method which, if I remember right, is shared only (though with paralyzant effect) by amyl nitrite. As the erectile tissue is dominated by the sympathetic, the whole phenomena, however, are fully explained by the established action of the drug upon that nerve.

Locally applied, it has slight (if any) effect upon the skin, unless denuded of epithelium. Superficial injection causes anæsthesia of the surrounding tissue to the extent of two to three inches, but deep injections affect the skin to a much less degree. When thrown down upon a nerve-trunk, while it affects the distal distribution, the centric portion, even a short space (immediately?) above the point of puncture, is uninfluenced. Dr. Corning has found when the local circulation, in a part into which a solution of cocaine has been injected, has been arrested either by an Esmarch

bandage or a tourniquet, the insensibility induced by the drug may be greatly prolonged, as thus the solution of cocaine is kept in contact with the filaments of the sensory nerves. When painted upon the mucous membranes, the tissues become paler and thinner, secretion is diminished, and sensation is completely annulled, the effect being greatest at the actual point of contact of the drug, and is in proportion to the strength of the solution used, and up to a certain point of the number of applications made. May this not be up to a limit of topical absorptibility (saturation)? It renders the conjunctiva and cornea completely insensitive, the ischæmia of the former being well marked, whilst it passes through the latter into the anterior chamber, as fluid extracted therefrom produces similar effects upon the other eye. "In eye under cocaine intra-ocular tension is decreased, and mydriasis is increased in a bloodless eye."

It dilates the pupil by local stimulation of terminal fibres of cervical sympathetic (the mydriatic nerve), and not by paralysis of motor oculi nor of circular fibres of iris. The degree of dilatation seems to vary. Knapp, of New York, reports, "pupil scarcely ever becomes as large as with atropine." Others have declared the mydriasis of atropine is increased, whilst I note one case of adhesions of iris, which had resisted atropine, broken up by use of cocaine.

"Accommodation is not wholly lost, the range of accommodation being shortened by recession of the near point from the eye, the far point not being appreciably influenced," its action being more upon the ciliary muscle than upon the iris (Knapp).

As a corollary to its contraction of the capillaries, the drug may yet develop useful qualities as an hæmostatic.

The contradictory reports of the action of the remedy may be reconciled, I think, either by exceptional idiosyncrasies, or from imperfect or insufficient methods of application, or from the use of inert preparations.

It should also be remembered that cocaine, being a product of organic chemistry, is liable itself to deterioration, microscopic growths nourished by the alkaloid destroying its efficacy, boric or salicylic acid being the best preventives of this change. The leaves also contain another principle, "hygrine," an active mydriatic (though cocaine seems to produce mydriasis independently of hygrine), also ecgonin, coca tannin, and coca wax, whose effects, but slightly known to us, may yet modify our conclusions. Those who

are interested in chemical analysis would probably be gratified to know that the formula for cocaine is  $C_{17}H_{21}NO_8$ , whilst in chemical terminology cocaine is a "methylbenzomethoxyethyltetrahydropyridinecarboxylate, whilst the impurity ecgonin is merely a methoxyethyltetrahydropyridinecarboxylic acid." Merck has succeeded in transforming benzoyl ecgonin into cocaine by heating several grammes with iodide of methyl and methylic alcohol, and then evaporating. The product conforms to all tests of genuine cocaine (THERAPEUTIC GAZETTE). Some of the samples used have been found to be adulterated with eserina, whilst another, which caused "a sharp urethritis" (Otis), was a druggist's impromptu mixture of the alkaloid with HCL. The fatal dose to man has not yet been reached. Twenty grains, taken with suicidal intent, produced vertigo, unsteadiness of gait, headache, nausea, vomiting, burning thirst, and abdominal gripings, all of which passed off in twenty-four hours.

I have applied from f3iv to f3vii (gr. 15 $\frac{3}{4}$ ) of four per cent. solution to my own buccal pharyngeal and nasal mucosa in the course of four hours, and frequently less amounts to myself and others of same strength. In the smaller amounts, say 3ii, there is a rather pleasing sedative effect, a sensation of well being and well doing, of content with yourself and your surroundings, which is sufficiently marked to afford a ready inducement to further appliance. This sedation has never with me run into somnolency, though others on whom I used small amounts *seemed* to experience such result, whilst in children, relieved by cocaine from toothache or earache, sleep, I think, naturally followed the freedom from pain. In the larger amounts there is to myself a sensation of intense cerebral activity, with augmentation of thought-processes, and especially with stimulation of imaginative perceptions and fancies, and I must confess there is a certain witchery which is apt to entice one to further indulgence. Sleep is totally abolished, whilst the continued application induces the rather actual wakefulness, with further a degree of restlessness, which finally becomes almost painful. There is also vertigo and nausea, going on to vomiting once after 3iss, and again after 3v had been used, and very decided tremor of the voluntary muscles interfering somewhat with the use of the pen. The skin is covered with profuse cold clammy perspiration; the pulse is bounding (120), beating full and strong; the brain is on fire, and throbs with unnatural excite-

ment. In fact, after using the 3vii from eight to twelve one evening I could only break myself from its further use by decided effort, and could not compose myself sufficiently to go to bed till about 4 A.M., where I tossed, with little sleep, till my usual hour of rising, and in the forenoon endured an intense prostration it has seldom been my lot to experience, which by noon compelled me to abandon my daily rounds and return home, where two or three hours' sleep restored my pristine vigor and appetite. I can appreciate now, as never before, the glamour of opium and cannabis indica, and the wretchedness of after-repentance. The loss of appetite is well marked even with smaller amounts, and this is not at all satiety, the repletion of a Thanksgiving dinner, but with slight nausea, a disgust of food, which prohibits hunger, though there is not "the hollowness" of simple abstinence from food. So far as these practical trials on myself go, I would, in view of endurance of excessive fatigue, rather depend on the latent energy of something (to me) far more substantial than cocaine. It should be remembered the above is practically overstimulation—the sudden thrust of an excess—upon an organization unused to any stupeficient, whether in the form of opium, tobacco, or alcohol. 3i of four per cent. solution contains about gr.  $2\frac{1}{2}$ ,  $\pi$ iii of four per cent. solution contains about gr.  $\frac{1}{2}$ , whilst a handful of leaves, say 3i, only gives up gr.  $\frac{1}{10}$  of the alkaloid. The dose by the mouth is gr.  $\frac{1}{2}$  to gr.  $\frac{1}{2}$ .

The rapid sketch I have given must suffice for the most part as indication of the range of usefulness of the drug. I cannot, however, too strongly urge that its anæsthetic effects are purely local, even that upon the nerve-trunk and the slight or negative effect upon the skin coming under this category, and that to secure the best results sufficient care must be exercised to convey the solution to the part indicated. It has been used successfully in operations upon the inner surface of eyelids and tear-passages, and on the eyeball in iridectomy, operations for cataract and glaucoma, etc., and even in enucleation. As a number of failures to induce complete loss of sensibility in the last mentioned use have been reported, allow me to add emphasis to my caution by a quotation of Turnbull's *modus operandi* (*Med. and Surg. Reporter*, November 9, 1884): "In a case of enucleation 2 drops of four per cent. solution of cocaine were instilled every three minutes until eight had been used. When Tenon's capsule was

opened, 1 drop of the solution was allowed to flow into the cut. As each tendon was caught up with the hook a drop fell upon it, and the successive tenotomies, each being preceded by a drop, were made at deliberate intervals. The large blunt-pointed scissors, curved on the flat, were next introduced from the nasal side, and with these in position, after thorough sponging, two or three large drops were so instilled as to flow down the blades, one on each side of the optic nerve as a guide. After waiting a minute, the optic, and with it the ciliary nerves, were severed at one stroke, during which the patient remained entirely quiet. There was less than the usual bleeding, and the healing was undisturbed" (Knapp, p. 26).

Outside of ophthalmology, the field is too extended for individual mention. The journals are replete with notes of cases. Some of the less obvious may be given a passing notice. Thus it finds a favorable application in acute otitis media, in removal of small tumors from various parts of the body, and in the lancing of abscesses. Papilloma of the larynx has been successfully removed with its aid, and operations for fistula in ano, vesico-vaginal fistulæ, and lacerated cervix and perineum have been painlessly performed. Dr. C. H. Thomas, of Philadelphia, claims for it the property of reducing inflammation and engorgement of the tissues in diseases of the endometrium (*Am. Journ. Obstet.*, February, 1886).

Circumcision has also been equally satisfactorily done. The mucous surfaces of the prepuce being first carefully cleansed, then slightly moistened, cocaine in powder is dusted on the surface to obviate pain from first stab of the needle, then hypodermics are given (four per cent. solution), 4 minims on dorsum, near frænum, and on each side (16 minims in all). Even an hydatid tumor of the liver has been opened and emptied under cocaine. In this case the patient was 72 years old, and ether was contraindicated by his general condition. Four per cent. solution was rubbed in for half an hour. Skin and subcutaneous fat passed with trivial pain. Fresh applications were necessary as muscles and peritoneum were reached. The operation lasted an hour. No shock and no peritonitis followed. Patient died on twenty-second day after operation, from inanition due to complete absence of bile from the alimentary canal. Soon after eating, the flow of bile from the sac was very great. The autopsy showed no peritonitis.

The dysphagia and violent irritative cough

of laryngeal phthisis have been ameliorated, thus giving us some control not hitherto possessed over these distressing symptoms, though not the complete mastery we were led to hope for. The relief of cutting pains of first stage of labor has followed its application to tissues about the cervix, whilst its endermic use has enabled the painless passage of the head through the ostium vaginae. In senile gangrene its application has relieved the severe pains of that dangerous disease. In confirmation of the action upon the nerve-trunk, Dr. Nash, of New York, injected  $\text{m} \text{viii}$  of four per cent. solution as near as possible in the infra-orbital foramen, reached through the mucous membrane of the mouth. There was complete anæsthesia of the left half of the upper lip and cheek, on both the skin and mucous surfaces, also a portion of the nose and left side of lower border of the gums, from the median line beyond the bicuspid. He inserted a gum wedge very firmly, causing no pain, and excavated and filled the tooth without giving the patient a sensation of pain, although before the injection the tooth was exquisitely sensitive. A similar result followed injection of 8 minims into infra-dental nerve at point of entrance into ramus of jaw. Messrs. Randolph and Dixon have used strong nitric acid saturated with cocaine as a painless escharotic, which may well be of service in venereal practice. An epithelioma has been treated by arsenical paste, the patient being readily able to endure its caustic action by reason of the remedy.

In leaving this part of my subject, I trust it has been well noted that the drug is not too rapid in its action, and that time should be given between successive applications for the preceding to take effect.

Of cocaine when taken by the stomach I have little to say, my own experience beyond operative measures and for irritative cough being designedly limited to its local use in hay-fever, of which I have spoken elsewhere. The many wines of coca are so bolstered with alcohol as to render it difficult to determine to which the effects (*if any*) are due. The fluid extract is reported to be a valuable adjunct for treatment of the morphine habit, but is not a specific. Cocaine is said to dilate the pupil contracted by morphine, and to allay the morphine hunger. In chronic alcoholism it is also serviceable, though a case reported to the Mississippi Valley Association of its treatment by gr.  $\frac{1}{2}$  hypodermically was followed by cocaine habit, the patient using gr. x daily.

The irritation when used hypodermically

is not greater than that from morphine,  $\text{m} \text{x}$  to  $\text{xv}$  (four per cent. solution) usually causing no constitutional symptoms beyond vertigo, pallor, and dilatation of pupil, whilst larger ones may cause nausea and vomiting also. The effect of the drug lasts according to the strength of solution and number and efficiency of applications.

It would not be strange in a remedy of such marked peripheric force, if investigation would show a further centric impression than is at present accorded to it, but of this additional observation is necessary. In the later journals reports of ill effects have not failed to appear. It is said exfoliation of the corneal epithelium, vesicular keratitis lasting several weeks, and panophthalmitis have succeeded its application. In other cases, general intoxication, nausea, and vomiting, lasting an entire day, stumbling gait, syncope (cerebral anæmia?), pallor and sweating, loss of consciousness, and convulsions are said to have ensued.

In one case that came under my own notice the use of upwards of  $\text{f}3\text{i}$  (four per cent.) applied to the nostrils was followed by a disagreeable dyspnoea (overstimulation of respiratory centres) lasting a considerable time.

Whilst it is by no means established that all the above are surely chargeable to the drug, there is enough to make us watchful and by no means indifferent to the possible results, even though the more grave effects may be exceptional, may be from excessive quantity or from individual idiosyncrasy.

It may be worth mentioning in passing that the case of poisoning from gr. x hypodermically (*Med. Record*, November, 1885), resembling morphine-poisoning, is not free from suspicion, owing to the large amounts of alcoholic stimulus injected.

A number of instances of addition to the excessive employment of the alkaloid have already been reported in our own country. Whilst we are not justified in jumping at any conclusion upon the evidence thus far presented, we are indeed urged the more to greater caution in its prescription both for others and ourselves, with added emphasis to the old adage, "A man his own lawyer has a fool for his client."

1523 GREEN STREET.

*A CASE OF TYPHOID FEVER COMPLICATED WITH SEPTICÆMIA.*

By K. MCKINNON, M.D., PLEASANT HILL, ALA.

MISS A. B., a maiden lady, aged 54, a dress-maker, who had been suffering more or less from dyspepsia, biliousness, and constipation for several years, complained of headache and fever the 9th of July, 1885. She first took some cathartic medicine, but the headache and fever continuing from day to day, I was called to see her the fifth day of her illness. I prescribed a cathartic and quinine to be taken two days, with the view of breaking the fever, thinking that possibly it might be of malarial origin. I visited her again the seventh day of her fever in the afternoon, and found her pulse 80, temperature  $103^{\circ}$ , and tongue covered with a thin white fur, still complaining of headache and loss of appetite. The cathartic had acted sufficiently, but the quinine had had no effect on the fever. I diagnosed the case to be typhoid fever. As I had nothing better, I prescribed 15-grain doses of salicylate of sodium as an antipyretic every two hours, until the temperature would be brought down to about  $100^{\circ}$ , when it was to be discontinued, and again given when the temperature rose above  $102^{\circ}$ . Sponging with cool water was also used at times to promote comfort and to keep down heat of the skin. The salicylate produced so much nausea that, after two days' use, it was discontinued (about six doses were given); the sponging was still used when necessary to moderate the temperature. Enemata of cool water were used once or twice a day to cool the bowels and keep them acting, as they were more inclined to constipation than diarrhoea.

During the ten or twelve days following there was very little change in her general symptoms. The pulse was from 80 to 86, and temperature from  $100^{\circ}$  to  $103^{\circ}$ . She took food with a fair appetite about every four hours, either milk or meat broths, and a half-ounce of whiskey before meals. I gave her little medicine. Part of the time I gave her 10 or 12 drops of oil of turpentine, or drachm doses of spirits of nitre every four hours. There was no tenderness in the bowels and little tympanitis. The appearance of the tongue improved, and became almost normal, except a little flabby.

She slept the greater part of every night, and took naps through the day. Her strength

was tolerably well preserved. She could get out of and into bed with a little assistance.

On the eighteenth day of the fever, at 7 o'clock P.M., her pulse was 86 and temperature  $101^{\circ}$ . Her general condition was about the same as it had been for a week past. I did not see her the following day, but visited her at 9 o'clock A.M. the next, the twentieth day of the fever. I discovered at once a change for the worse. I found her pulse 90, temperature  $103^{\circ}$ . Her nurse informed me that her fever had been somewhat higher the preceding day than it had been for several days, and she slept less than usual the night before. I tried the salicylate of sodium again, together with the sponging, to reduce the increasing temperature. She had been using ice and iced water for several days. The same day at 3 o'clock P.M. I was hastily called to see her, and found her suffering from greatly increased fever, with violent rigors, pulse 125, and temperature  $105^{\circ}$ .

The fever gradually subsided that evening, followed by a free perspiration. I gave quinine the two following days, and there was no more return of the rigors, but there was a very marked change for the worse in all her symptoms. The day after the pulse went down to 90, but gradually increased in frequency and lost in strength. The temperature also lowered, but during the following week it fluctuated from day to day, sometimes as high as  $103\frac{1}{2}^{\circ}$  and then down to  $100^{\circ}$ , but with no regularity. An aperient was given the evening the rigors occurred, and the bowels were freely moved. The passages after this became very offensive, notwithstanding the bowels were kept freely moving by means of aperients and enemata. I gave her resorcin as an antiseptic for three days without any effect in correcting the offensive smell of the passages. From the evening she had the rigors, subsultus was so violent and constant as to greatly interfere with her resting. She had none of it before the relapse. Her tongue became coated with a brown fur; sordes accumulated on her teeth and lips. There was complete anorexia. Small quantities of food were retained, but the whiskey, brandy, and medicines were rejected. The stomach became almost intolerant of everything. Her strength rapidly failed; her jaw dropped when dozing; there was great apathy and dulness in her expression, and marked lethargy. I noticed that she eructated occasionally before the relapse, but frequently afterwards. The bowels became quite tympanitic, without much tenderness. The skin

was constantly moist, but no free perspiration until a day or two before death, which occurred on the twenty-eighth day of the fever.

Instead of giving the daily symptoms of this case, I have thought it best to group them, as they were very uniform, into the two periods, before and after the relapse. I wish to call special attention to the sudden and unexpected symptoms developed on the twentieth day of the fever from a condition indicating no great danger to one of the gravest without any very obvious cause. She was carefully nursed. I do not believe the exacerbation of fever and violent rigors, which occurred on the twentieth day of the fever, were caused by malarial poison. She had been living for several years in this village, where there is so little malaria that it is a very rare thing for any one living here to have a mild attack of intermittent fever. How, then, are we to account for this exacerbation and relapse? In my opinion it was a case of septicæmia, caused by septic matter in the bowels being absorbed into the system through the denuded or raw surfaces of the enteric glands after they had cast off their sloughs in the course of the typhoid disease. Her food was almost entirely of milk and meat broths, taken at regular intervals, in such quantity as it was thought she could digest. The probability is that she took more than was digested, and that it was retained in the bowels too long, until septic changes supervened, and the poison there developed was then absorbed into the system. I have been in the habit of giving iodine and carbolic acid in typhoid fever for their antiseptic properties, but did not in this case. I now think that if I had given some antiseptic, and a few doses of castor oil between the tenth and twentieth days of the fever, to clear out the bowels, the termination of the case might have been different. Her bowels were inclined to constipation before the relapse, but afterwards were easily moved. At no time was there much diarrhœa.

In the spring of 1853 I treated a case of pyæmia in a young man just convalescing from a violent attack of typhoid fever. It was manifested by the formation of cold abscesses in the subcutaneous cellular tissues in different parts of the body. That case of pyæmia and this with well-marked symptoms of septicæmia are the only ones of their kind that have come under my observation in a regular practice of thirty-four years, in which time I have had a fair proportion of typhoid fever to treat. No doubt many patients were affected with the poison of septicæmia in a mild de-

gree, or the symptoms of it were so obscured by other complications that they were not duly appreciated in the treatment.

It is only of late years that autoseptic poisons have been carefully studied, so that it is not surprising to find so little in the books about them. But now that they are known to exist, though their true character may not yet be satisfactorily ascertained, the important consideration with the practitioner is how to prevent them. The indications to prevent this particular accident or complication would seem to be to keep the bowels gently moving by aperients when there is a tendency to constipation, and to use antiseptics to prevent or to correct septic changes taking place in the contents of the bowels.

---

#### NOTES FROM GENERAL PRACTICE.

BY FRANCIS L. HAYNES, M.D., PHILADELPHIA.

---

#### II. AN EASY METHOD OF PLUGGING THE POSTERIOR NARES.

A PIECE of fine silver wire, fifteen inches long, is doubled; the closed end is left rounded and the free ends are neatly twisted together. A slight bend is given to the bar thus formed. A stout thread, twenty-five inches long, is tied to the twisted end.

The patient sits in front of the physician, his head thrown slightly backwards, so as to make the passage of the wire into the pharynx more easy. The parts are illuminated by the forehead mirror, unless a good supply of daylight can be used.

The blunt end of the wire (with the concave aspect downwards) is pushed along the floor of the nasal passage, and through the naso-pharynx until it is seen in the pharynx, the patient assisting by holding the tongue with a depressor. The end of the wire in the pharynx is now grasped by Gross's polypus forceps, the fingers, or anything else convenient, and pulled through the mouth. The thread is cut, and a piece of absorbent cotton, slightly compressed, large enough to fill the posterior nares, is tied to it, about ten inches from its mouth end. The tampon is pulled into position by drawing on the nasal end of the thread. The plug is generally caught by the edge of the soft palate, but can easily be guided past it by the finger. The nasal and mouth ends of the thread are tied together, so as to form a loop, which is hung over the nearest ear, so that it may be out of the road.

In a recent case, not happening to have any wire with me, I managed very well with a piece of straw from a broom, one end of which was bent over into a rounded loop and tied thus, so that it might not catch in the mucous membrane.

The nostril is then obstructed, if necessary, by means of a mass of cotton, which will readily stay in place without tying.

If it can be avoided, the tampon should not be left in place more than three hours, as its presence is exceedingly uncomfortable to the patient, whose strength rapidly fails under its use. By carefully noting which nostril pours forth the greatest quantity of blood, one side may generally be left patent, to the great advantage of the sufferer.

I generally allow the patient to remove the plugs himself, and he is requested to do this gradually, first the anterior, and fifteen minutes after the posterior plug, by gently pulling on the string issuing from the mouth.

The removal is timed so that it will precede by a short interval a professional visit, so that the physician may determine whether it is necessary to renew the plugs.

In cases of intermittent nose-bleeding in anæmic subjects, the thread lying in the passage may be renewed by tying a fresh piece to the one that has become foul, and thus left for twenty-four hours or more, ready for a fresh attack. The presence of the thread is but slightly inconvenient, not interfering with eating or drinking. An intelligent attendant can readily be taught to draw the plugs into position, and during the intermission the patient can enjoy the luxury of breathing through his nose.

This procedure may be executed with so much ease and rapidity that there is less excuse for the prolonged presence of the plug than when the barbarous instrument known as Bellocq's canula is used.

The plan of packing the nasal cavity (suggested by an eminent authority), by a long piece of lint pushed in from the front, I have found inefficient, difficult, and very uncomfortable to the patient. The removal of a plug thus placed is almost sure to provoke fresh bleeding.

An additional advantage is that the nasal passage can be traversed by the wire, notwithstanding extreme deviation of the septum.

This little operation should be preceded by the free use of cocaine spray to nose and pharynx, which will entirely prevent gagging, and it is to be hoped will prove by further experience to be in itself a valuable hæmostatic.

1924 E. CUMBERLAND STREET.

# *MINERAL WATERS OF MT. CLEMENS, MICH., IN LEUCORRHOEA.*

By A. N. SHOTWELL, M.D., MT. CLEMENS, MICH.

LOOKING over all authors at hand, I find American authors, with but few exceptions, do not speak of mineral waters in leucorrhœa. Most all mention sea-bathing, but put more stress on some new mode of applying medicines.

So it has come to the pass that one is almost unable to pick up a medical journal without finding some new advertisement for pessaries, syringes, etc., for the quick and radical cure of all female troubles.

After nearly two years and a half experience at this spring, I find that a large per cent. of the females who come here are suffering with this complaint,—nearly eighty per cent. of all females between the ages of sixteen and fifty years.

I think leucorrhœa is usually spoken of as a symptom and not as a disease, yet nearly all treat it as a disease by various astringents, etc. So it has come to be the fashion to probe, burn, and dilate the poor woman's womb from the time she is old enough until she dies.

I cannot help quoting a medical friend who for years had a large female practice, who said, "Let the poor womb alone and build up the general health, and your patients will be the better for it."

This I have found only too true in practice.

Of the various modes of treatment which have been brought before the profession in the last few years, many have proven useless in a great many cases.

Some through false modesty, some from lack of means to go to a specialist, some too remote, and others from failure to get any relief, have gone through life, a curse to themselves and those who have had to live with them, or have become victims of patent medicines.

Exciting causes seem to be all those disorders which cause stagnation in the proper circulation of the blood, as heart- and lung-diseases, chronic constipation, etc. Direct irritation, such as sexual excess, pessaries, excessive dancing, skating until warm and then sitting in draughts, tight lacing, bad air of any kind, general debility of the system, as well as morbid conditions in general.

The symptoms of an acute attack are ushered in by slight fever, drawing pains in the small of the back and inguinal region, with a feeling of fulness in the pelvis. Ex-

ternal pressure upon the lower part of abdomen is painful, there is more or less fever, and after three or four days the patient observes a discharge from the genitals, which at first is transparent and sticky, staining the linen grayish, by and by becoming opaque, and more or less purulent. In the further course of eight or ten days the fever gradually subsides, and after that the discharge diminishes until it finally ceases, or runs into a chronic form, of which we will now have to treat.

Patients will now run from the above into a state where there will be clots of a gelatinous mass constantly passed. This is characteristic of uterine catarrh. The discharge will sometimes collect in the neck of the uterus, and be expelled with pain, constituting uterine colic. In time it may affect the monthly period in various ways, in the shape of dysmenorrhœa, amenorrhœa, metrorrhagia, neuralgia, hysteria, and insanity. Or we may have it take another form in the shape of excoriation and pruritus, etc., which will make life a burden. We find it in some showing itself in an irritable temper, general weakness, patient unable to take any exercise without extreme fatigue; any labor, such as light household duties, will cause extreme fatigue; they will complain all the time; life becomes a burden; so irritable will they become, that it is a fruitful source of divorces.

Looking over the various works on female diseases, I find no mention of saline sulphur-waters in chronic leucorrhœa, with the exception of Walton,—"Mineral Waters of United States and Canada," a very excellent work.

I find most all American authors speak of sea-bathing, mountain air, quiet, etc., but not any mention of saline sulphur-bath in any form. Most European authors speak of some of the German spas.

Now, after an experience of upwards of two years here, I find the most decided benefit in all forms of congestive, catarrhal, and various kinds of leucorrhœa.

CASE I.—Miss E., æt. 32, had been suffering for some time with pain and soreness and general weakness, with profuse leucorrhœa, in character white and gelatinous discharge at each period; suffered a great deal of pain, so much so I was called in, May, 1884, and July, 1884, to prescribe then and afterwards for the relief of pain. I recommended baths at 98° F. Only took two or three, as they gave immediate relief.

In February of the following year she had malarial fever, and then commenced the baths

regularly, and took twenty, and since that time has not had any trouble, has gained flesh, and has no more pain at the monthly periods, and is in perfect health to date.

CASE II.—Mrs. X., æt. 35, mother of two children, contracted gonorrhœa three months before I first saw her. When I first made an examination, in July, 1885, the discharge was so profuse that it would drop from the vagina while on the street. On examination I found extensive ulceration of the vagina and os. I recommended baths at 98° to 100° F. strength, sp. gr. 1033, with hot mineral-water injections twice daily, and I used daily applications of a strong solution of bichlor. mercury. After taking twenty-five baths she was entirely restored, and returned home.

CASE III.—Miss Y., æt. 18, came, complaining of a profuse discharge. On examination I found it mostly confined to the external genitals and urethral orifice. Recommended baths, with injections, and in this as well as the above case I used local applications of bichlorid. mercury. After eight baths she went home well.

CASE IV.—Mrs. H. came for the benefit of the baths in gouty rheumatism of several years' standing. She was of a peculiar nervous temperament coupled with bilious condition, and there was a great deal of deposit in and around the joints of both hands; she also had a profuse leucorrhœa, which she had given up in despair of ever getting over, so the fact was not mentioned when she came. Prescribed baths for rheumatism at a temperature 100° to 105° F. After taking twenty-eight baths both troubles were well, and she returned home.

CASE V.—Mrs. A. came in February, 1886, with her husband, who was suffering from rheumatism; she also was suffering a little herself, so she thought she would take a few baths. She had chronic leucorrhœa for ten years, and had consulted physicians of New York City and Rochester, and had undergone systematic treatment without any benefit. After taking eighteen baths had no more trouble. Did not take any medicine of any kind, nor was there any other treatment.

CASE VI.—Miss G., æt. 18, came under treatment in March, 1886; complained of excruciating pain in ovarian region of left side, with numbness of limbs, bearing-down pain; said she felt as if everything was falling out of her. Had profuse leucorrhœa, and so much soreness that I was unable to use a speculum. Upon digital examination I found a great deal of displacement with enlarge-

ment of os. I kept her in bed and used hot mineral-water injections. In four or five days the soreness had so far subsided that I was then able to make a thorough examination, when I found a great deal of inflammation with ulceration of os and with great tenderness of ovaries.

I used locally iodoform and subnitrate of bismuth and supported her uterus with a pessary, and used baths at temperature 101° F., for twenty minutes; two baths a week. Now at present writing patient has no further trouble, except slight leucorrhœa when she takes cold, but it only lasts for a few days at a time, and she is no longer obliged to wear a pessary.

CASE VII.—Mrs. W., æt. 29, mother of two children, presented herself April 24, 1886. I found her very much prostrated, with the following history: About four years ago she had a discharge from the vagina; had no examination, and did not know what it was. After a short time a copper-colored eruption came on the breast and limbs; following that in a short time was great deal of pain in limbs below the knees, profuse discharge, with great amount of pain at each period. When I made an examination I found the cervix greatly enlarged, lateral rupture with extensive ulceration, which would bleed profusely from a mere touch. I commenced treatment with baths with temperature ranging from 96° F.; sp. gr. 1032. Patient only bathed every other day. After commencing baths the discharge increased for a time. In the mean time I used locally iodoform and 10-grain doses of potassic iodide five times daily. After taking twenty-eight baths patient was well enough to go home, and continued medicine internally with no need of any further treatment.

CASE VIII.—Mrs. R., æt. 30, came May 20, 1886; complained of extreme weakness, pain in chest and stomach. Pain in stomach was so severe that she could not do any work, pains coming on about every seven days, but she never was free from it, and at each monthly period was always confined to her bed from two to five days. As the pain was so much worse in the stomach at these times, I looked upon it as a case of sympathetic irritation. On examination, I found chronic vaginitis and a great deal of ulceration of os with enlargement, with great deal of discharge. Internal measurement of uterus was three inches, otherwise organ was in proper position; there was a good deal of ovarian tenderness.

I commenced treatment by the application

of iodoform internally to uterus, and to the vagina subnitrate of bismuth and glycerin, and baths at temperature of 98° F., sp. gr. 1033, for one week, then increased to one-half strength, sp. gr. 1066, and now is taking, third week, full strength, 1132. She has no more pain in chest and has but little discharge, and from an anæmic woman she has changed to one with red cheeks and has gained flesh, and is well and cheerful and has returned home.

#### ACTION OF RHODAN.

We abstract from *Schmidt's Jahrbücher*, April, 1886, p. 133, the results of DR. PASCH-KIS's experiments on rhodan soda, a rarely used but apparently powerful drug.

In frogs the injection of 5 c.c. of a twenty per cent. solution causes tetanic convulsions of a long duration, recalling the effects of strychnine application. Respiration and heart-beat stop. If 3 drops of a three per cent. solution of the drug are placed upon the exposed heart of a frog, the pulse sinks gradually from 46 to 14 beats per minute, until after the lapse of twenty-five minutes cardiac action is arrested, which can be recovered, however, by the aid of atropine. The action of the drug proceeds from the spinal cord. In mammals the drug causes an increased reflex excitability, becoming ultimately tetanic in nature, but differing from the strychnine tetanus by proceeding more slowly. Injected into the carotid artery or jugular vein of rabbits and dogs, rhodan produces a considerable and lasting increase of the arterial pressure. Peristaltic intestinal action becomes also intensified by the drug, and, as observed in the rabbit, urination increases likewise.

#### SUBCUTANEOUS INJECTIONS OF SALICYLATE OF COCAINE IN ASTHMA.

PROF. MOSLER, of Greifswald (Prussian University), details in the *Deutsche Med. Woch.*, 1886, No. 11, a number of cases of asthma which were cured by the hypodermic administration of salicylate of cocaine. Bromide of ammonium given in the ordinary doses together with the injections appeared to intensify their usefulness. The paroxysms were in nearly every instance lessened and shortened, if not entirely removed. It is noteworthy that after one hypodermic injection of the cocaine salt ( $\frac{1}{4}$  grain) rigors and vertigo, which lasted for three-quarters of an hour, set in.

### PERFORATIVE PERITONITIS.

ALTHOUGH correct diagnosis is of immense importance in the treatment of any disease, in but few is it as vital as in perforative peritonitis. If ever the appendix vermiformis be opened the chances of recovery are greatly increased by surgical interference, whereas to cut into an inflamed peritoneum, when the bowels were sound, would greatly enhance the risk of a fatal issue. Diagnosis treads here so closely upon the heels of treatment, or, to speak more accurately, treatment follows so closely in the footsteps of diagnosis, that we make no apology for calling the attention of our readers to the subject. In a very elaborate paper, read at the recent meeting of the Association of American Physicians by Prof. Fitz, but not yet published, the advantage of early laparotomy in properly-selected cases was plainly shown, but the selection—*i.e.*, the diagnosis of the cases—offers the greatest difficulty. Abrupt suddenness of onset sometimes aids us, but not always, for an appendicitis may steal slowly upon the patient, and an idiopathic peritonitis may develop very rapidly. A rapidly-developed localized tumor in the ileo-cæcal region, preceded by evi-

dences of local inflammation, is sufficiently characteristic to warrant surgical exploration, but owing to the tendency of the pus to drain downward, and the inflammation to follow it into the pelvic character, no distinct tumor may result from a perforation of the appendix.

When tympanitis in a general peritonitis is excessive, masking hepatic and splenic dullness, pushing out beyond the ribs and encroaching on the lungs by thrusting upward the diaphragm so as to interfere with the breathing, then suspicion of gas in the peritoneal cavity should be aroused. In such cases it becomes essential to determine whether the gas is within the bowels or on their outside. Various tests have been proposed from time to time for the purpose. But in a recent article in the *Deutsches Archiv f. Klin. Med.*, Dr. E. Wagner shows that almost all of them are uncertain, if not valueless. The fistula rule of Tschudnochowski can rarely be heard when there is perforation, because very rarely is there a to and fro rush of air through the intestinal fistula in response to the respiratory movements of the diaphragm. Absolute clearness of percussion, dullness over the liver, seem only to be at all diagnostic of air in the peritoneal cavity when it is known to have been suddenly developed. Changes in the percussion note accompanying corresponding alterations of the body, when distinctly obtained are characteristic of the conjoint existence of air and fluid in the peritoneal sac; but a patient with a furious acute peritonitis is not to be rolled about and thumped as though he were a beer-barrel, or even as though he had a pleurisy. Usually the sign cannot be made out. In regard to succussion, even the thought of attempting to obtain it has a tincture of brutality.

The one diagnostic sign, according to E. Wagner, is the complete absence of any intestinal peristalsis revealed by palpation and auscultation of the abdomen. When there is gas in the peritoneal sac, it collects in the upper portions of the abdomen, so that when the patient lies upon his back, it interposes between the bowels and the listening ear a stratum of badly-conducting substance. Where, on the other hand, the gas is within the gut, the folds of the intestines are forced into intimate contact with the abdominal walls, and every movement of these walls is transmitted.

Fortunately, in doubtful cases, the careful pushing of a fine, not too short, trochar into the abdomen will enable us to come to a decision. If foul-smelling gas, or liquid having

a fæcal odor, escape from the trochar, the case is plainly one of perforation, provided care has been exercised not to perforate the intestine. When the trochar is surgically clean and small enough, no harm can come of this exploratory puncture, so that it is a safe and most important procedure.

#### PASTEUR AND HIS INSTITUTE.

**H**ISTORY teaches that the world's leaders in thought and science, its greatest discoverers, in brief, all men who strove most for the welfare and advance of the human race, have perpetually been met with scepticism, if not with derision and open abuse. In the deadly conium-draught of Socrates, the ignominious fetters of Columbus and Galileo, and in the fierce resistance against the reformers, we recognize alike this principle of constant and singular antagonism of the world against the doctrines and discoveries of its greatest minds. This principle of antagonism, which also applies to the medical sphere, is, however deplorable if carried to extremes, still not wholly exempt from salutary aspects, for it represents a firm check for the charlatans of science and the pseudo-benefactors of mankind, while against doctrines of actual truth and advance all resistance must in time prove vain. To maintain a dignified reserve in face of announced innovations or discoveries is well becoming to the laborers in the field of science, but an opposition persisted in after theories have become facts which can be practically demonstrated, or after discoveries have proven their actuality by crucial tests, has no claim to existence.

In medicine, the doctrines of Jenner in the last century, and of Koch and Pasteur in our days, have in their turn been more severely fought and objected to than the teachings of any other medical men of recent times; still, it can with safety be asserted at the present day that no amount nor degree of resistance will ever destroy the scientific structures erected by these men. The merits of Jenner and Koch are no longer a subject of discussion with the profession, at least with the vast majority of its authoritative elements, and Pasteur alone is still before the professional forum to receive its judgment. Inquiring into the antecedents of Pasteur, we find him to be no *homo novus* in the field of practically applied pathological researches; his successful labors in regard to the treatment of milzbrand, chicken-cholera, and ery-

sipelas of hogs have spread his fame far beyond the borders of his native country. No wonder, then, that his memorable announcement before the Academy on the 26th of October, 1885, of having found a method of preventing hydrophobia went far in enhancing his already established reputation and in popularizing his name all over the world. Joseph Meister, the young Alsatian, who on the 4th of July, 1885, had been bitten by a dog, the rabid character of which had been officially ascertained, attained complete immunity from the dreaded consequences of the accident. Jupille, the shepherd-boy, on whom Pasteur tested his preventive method next, was equally fortunate as Meister. No sooner had the news of Pasteur's auspicious discovery been published, when from all parts of Europe, and even from America, numerous persons who had been bitten by mad animals, chiefly dogs, sped to Paris, in order to receive from the hands of Pasteur protection and immunity. Let us without a commentary now follow up the facts as they gradually developed themselves.

On the 1st of March, 1886, Pasteur communicated to the Academy his further observations and results obtained by his preventive treatment of hydrophobia. From July, 1885, to February, 1886, three hundred and fifty persons, bitten by mad dogs, were vaccinated by Pasteur and his assistant, Grancher. Pasteur remarked in the course of his address that although his laboratory had for the past five years been devoted to the study of rabies, and had become, as it were, the centre of all information and observation pertaining to this affection, he shared the universal surprise in finding how large the number of persons bitten by mad dogs actually was. The ignorance of this fact can in Pasteur's judgment be referred to two principal causes. As long as hydrophobia was regarded as an incurable disease, the rabid character of the dog was usually kept secret from the bitten person in the assumption that this knowledge would create a certain unavoidable predisposition for the affection in the person. Besides, in the case of working-people it was feared that if the fact of the bite should become known to the employers and fellow-workers, the bitten person would lose his position, on the ground that he might become dangerous at any moment. This latter view is of course an erroneous one, as hydrophobic subjects are only dangerous during the last stages of the affection.

In order to obtain definite and convincing

results, Pasteur resorted to very stringent precautions. In the first place he demanded invariably a certificate of a physician or a veterinary surgeon testifying to the rabid nature of the dog. In some exceptional instances only Pasteur was obliged to dispense with this requisite. Furthermore, no patient was admitted for treatment in whom the skin did not give distinct evidences of having been pierced by the teeth of the animal. In several cases Pasteur could himself prove the rabies of the animal by inoculating nervous tissue taken from the killed animals into rabbits or guinea-pigs.

Of all persons hitherto vaccinated, nearly one-half have passed the period in which the symptoms of hydrophobia as a rule manifest themselves (viz., forty to sixty days) without presenting any morbid appearances. Of the cases as reported upon to the Academy by Pasteur, one deserves special mention, as it indicates the success of Pasteur's method even under particularly aggravating circumstances. A boy 8 years of age, Jullion by name, being attacked on the 30th of November, 1885, by a mad dog, and beginning to cry, was bitten by the dog, the lower jaw of which entered the open mouth of the boy. The result of the bite was a deep laceration of the boy's upper lip, gums, and cheeks. Cauterization was impossible; the rabid character of the dog was promptly ascertained by a Parisian veterinary surgeon. The boy was presented to Pasteur for treatment, and at present enjoys perfect health. In one case only death ensued after treatment. Louise Pelletier, 10 years of age, was bitten on the 3d of October, 1885, by a powerful shepherd dog, and not until after the expiration of thirty-seven days was sent to Pasteur for treatment, with deep wounds covered with a bloody purulent secretion in the head and shoulder. Though aware of the uselessness of treatment in a case presenting itself five weeks after the bite, and under such adverse conditions, Pasteur, for humanity's sake, admitted the girl for treatment. On the 3d of December the girl perished, as predicted by Pasteur, under symptoms of hydrophobia.

Pasteur's treatment appears in no instance of the three hundred and fifty patients vaccinated, to have given rise to any untoward symptoms. No abscess nor phlegmonous inflammation has ever been observed as resulting from the vaccination; in some instances only a slight œdematous reddening showed itself.

We are now to decide the vitally important

question whether or not Pasteur's preventive treatment of hydrophobia is to be regarded as a safe protection against the dreaded affection. Before answering this query, let us see how Pasteur's method and results are received in other quarters. The French press, both the professional and secular, as might be presumed, is unanimous in endorsing Pasteur's practice as the *par excellence* achievement of medicine of the century. But knowing the sanguine propensities of the French nation in matters apt to verify the famous *nous marchons à la tête de la civilisation*, we take the verdict of the French press *cum grano salis*, and turn our attention to the country of severe and critical judgment, Germany. When the subject of the "Institute Pasteur" came up for discussion in the German Parliament, the minister of state, V. Gossler, appointed Virchow to report on this matter. "The results of Pasteur's practice," quoth the Nestor of pathology, "are most gratifying, and while the time has not yet come to deliver a final judgment on the matter, it deserves our fullest attention and support."

The Austrian press is divided in the matter, though after the return of Prof. v. Fritsch from Paris and his commendation of Pasteur's work, the Viennese medical journals support Pasteur. Russia, England, and other countries have likewise sent medical missionaries to Paris in order to study Pasteur's method.

Viewed as a whole, the competent voices of the profession, while still observing a certain reserve, do not hesitate to acknowledge that the results hitherto obtained by Pasteur justify the most favorable anticipations. We are undoubtedly safe in following the *aurea mediocritas* as prescribed by the judgment of Virchow. While regarding the work of Pasteur with the interest due to both the therapeutic progress and the practical benefits it embodies, we wish to defer our final judgment in the matter to a later date.

The establishment of an institute in Paris, as suggested by the wisdom and humanity of Pasteur, in which not only all persons imperilled by hydrophobia could be treated and cared for, but which at the same time would be a focus for all pathological investigations basing on the vaccination principle, has, alongside of most liberal financial contributions, excited a good deal of adverse criticism regarding Pasteur and his work. There are those who in fierce zealotry do not hesitate to call one of the greatest pathologists of all ages a fraud and a charlatan, and refuse all support, moral and material, to the "Institute

Pasteur." Nevertheless, the "Institute Pasteur" will be erected most certainly, thanks to the liberality of Freycinet, the French secretary of the interior, and the most generous contributions from all parts of the world that are being sent to Paris. The high objects aimed at, its liberal and international character, and the competency and integrity of its chief, insure for the "Institute Pasteur" a highly auspicious and lasting prosperity.

#### CALOMEL AS A DIURETIC.

DR. ERNST JENDRÁSSIK, assistant to Prof. Wagner, of Budapest, has created a genuine surprise by his exposition of a virtue residing in calomel, which has hitherto remained wholly unknown (*Deutsches Archiv für Klinische Medizin*, April 22, 1886). In fact, though some elder writers recommend calomel in dropsy, and also allude to a certain diuretic action of the drug, this property is not even mentioned by any of the text-books at present in use. Wherever calomel is now being used in the treatment of dropsy, its drastic action alone is taken into consideration.

Being called upon some two years before to treat a case of dropsy, in view of the wholly obscure causation of the affection and the strong suspicion of a syphilitic basis, our author instituted a mercurial treatment, beginning with inunctions of blue ointment, soon followed by small doses of calomel in combination with jalap. Scarcely two days had elapsed after the calomel treatment when the urine was voided in such quantities that the dropsical infiltration completely disappeared in a few days. A relapse of the dropsy a couple of weeks later was with equal promptness cured by the exhibition of calomel and jalap. This discovery, of course, led Jendrassik to further researches in dropsical cases, in which the diuretic action of the drug was distinctly established.

Our space, however, prevents us from publishing the clinical records of seven other cases of dropsy, the recovery of which is definitely traced to the powerful diuretic action of calomel.

Calomel was generally given combined with jalap, though this addition is of no importance. Urination increased up to 9500 c.c. in twenty-four hours, the polyuria usually being proportional to the extent of the œdema present. Jendrassik found that 3-grain doses, given three to five times daily, showed the

promptest effects. It is important and interesting to note that the diuretic action of calomel only shows itself simultaneously with the appearance of the symptoms which indicate the absorption of the mercury. The diuresis appears three days after having taken the drug, and persists until the œdema has completely disappeared.

Control experiments proved that in the combination doses of calomel and jalap, the diuretic effects referred alone to the first constituent, as the latter never produced these results when given alone.

The degree of the diuresis was found to be dependent upon two factors,—first, upon the size of the dose ordered; and, second, upon the extent of the dropsy present. It was observed that the diuretic effects proceeded *pari passu* with the manifestations of mercurial absorption, such as metallic taste in the mouth, increased salivation, stomatitis, etc.

Many of the observations of Jendrassik are too interesting to be wholly omitted.

Employing doses of 2 to 3 grains of calomel, he invariably obtained the diuresis, while larger doses, 6 to 7 grains, always failed. Our author justly concludes that in this, as in other instances, the effects of a medication depend not upon the amount of medicine ingested but upon the amount absorbed. In the instance of calomel, larger doses provoke diarrhœa, and thus to a large extent prevent the absorption of the drug. But little time appeared to intervene between the taking of calomel and the appearance of its diuretic effects. If given in the proper dose, the diuresis appeared usually within a couple of days. At the same time, it was noted that a certain quantity only of calomel was required to effect the diuresis, and that any further surplus was wholly ineffectual, especially when polyuria had already set in.

The author can give no clue to the manner in which the diuretic action of calomel in dropsy is effected, since neither the heart nor the kidneys are directly influenced. Experiments made with calomel (and also with jalap) on healthy individuals remained wholly negative; stomatitis and salivation set in, but no polyuria. The same failure was obtained in a case of pleuritic exudation with diminished urination. Still, the hypothesis (as a result of exclusion of other modes) is ventured upon that the primary factor in the diuretic action of calomel is the resorption of the œdematous fluid by the blood.

In high grades of dropsy depending upon

heart-disease, the drug evolves its highest diuretic powers; in cases of slight œdema, in pleurisy, and in the œdema of kidney-disease, the drug fails.

In conclusion, the undesirable after-effects of calomel, such as diarrhœa and stomatitis, are briefly referred to, and means suggested to obviate them. Against the diarrhœa a small dose of opium ( $\frac{1}{4}$  grain) acts as a sufficient check, without influencing the diuresis. Stomatitis is to be met by the use of chlorate of potassium given as a gargle, or, if this be insufficient, internally (12 grains daily). We have before in a previous issue (July 15, 1886) alluded to Jendrassik's results, but his recent studies seem to entitle his views as to the diuretic action of calomel to marked attention.

#### ON STERILIZED HYPODERMIC INJECTION FLUIDS.

THE interesting question of preservation of the solutions destined for hypodermic injections has for a long time occupied the minds of physicians and pharmacists. Various schemes and appliances have been resorted to to arrive at a practical solution of the problem. We mention the distilled aromatic waters, the addition of alcohol, glycerin, and salicylic acid to the medicinal substance. But the fear that these additions could exert a modifying or altering influence upon the injection fluid has always prevented anything like a general adoption of such measures.

Again, the extemporaneous injections which have been proposed from pills, lozenges, or gelatin-cakes, presented the same objectionable features, and never gave clear and pure solutions. Filtration had to be excluded on account of the minute quantity of the liquid needed, which would probably for the greater part be retained on the filter. The ordinary solutions prepared in advance have the great objection of rapidly undergoing a process of decomposition, not to speak of the eventual changes in the concentration of the fluid.

As it is nevertheless a matter of great convenience for the practitioner to dispose of ready-made solutions, which, in cases of urgency, can be administered at once, we are glad to inform our readers that this has been accomplished under strict exclusion of the disadvantages above alluded to.

Two pharmacists have almost simultaneously, but certainly independently of each other, solved this important matter by the adoption of the same principle,—i.e., steriliza-

tion of the fluid. Dr. Friedländer, of Berlin, and M. Limousin, of Paris, will be entitled to equal shares of the credit of this invention, the former having shown his sterilized injection receptacle confidentially to our Berlin correspondent in the latter part of April, 1886, and the latter publishing a description of his "ampoules hypodermiques" on the 15th of April, 1886, in the *Bulletin Général de Thérapeutique*.

Limousin's "ampoules" have the form of a small and somewhat ovoid balloon, terminating in a fine neck. The interior of these receptacles is sterilized by the method of Koch and Pasteur, viz., subjecting it to a temperature of 200° C. Then the medicinal fluid is introduced by placing the point of the neck while warm into the cold liquid, or by injecting the liquid warm by means of a small syringe with a fine nozzle. The receptacle being filled, it is closed by placing its open mouth into the jet of an oxyhydrogen lamp. This procedure insures absolute sterilization of the vessel and its contents, and prevents both physical and chemical changes in the latter. The solvent liquid besides is previously filtered by the Chamberland filter. If the injection is to be made, the receptacle is placed on some supporting article, its neck broken, and the nozzle of the hypodermic syringe introduced. Solutions of morphine and ergotine, which otherwise would have been doomed to a speedy decomposition, have in this manner been preserved intact for a year. In the winter it is advisable to warm the receptacle gently previous to using it, in order to redissolve the crystallized particles of its contents. Limousin credits Dr. Duhomme, president of the Society of Therapeutics of Paris, with the authorship of the idea practically executed by himself.

Dr. Friedländer, intending to exhibit his aseptic solutions at the September meeting of physicians and naturalists at Berlin, has naturally, as yet, avoided giving publicity to the working plan of his process. But, thanks to the courteous liberality shown by this gentleman to the Berlin correspondent of the GAZETTE, we are privileged to familiarize our readers with the essential features of Dr. Friedländer's process.

Though in plan and principle the methods of the German and French chemists present no material deviation, a comparative examination will readily yield the superiority to Friedländer's process. Our correspondent from Berlin describes his *modus operandi* from a personal experience in the laboratory as

follows: Little glass balloons of an equal size, with an elongated neck and a somewhat flattened bottom, are sterilized for three hours on three consecutive days in a glass jar, the mouth of which is closed by a tightly-fitting sublimate cotton stopper. A temperature of 200° C. being required for this sterilization, an olive oil bath has to be resorted to. The water intended for the solution of the alkaloid is also sterilized by being raised in a water-bath to 100° C. After this radical sterilization of both water and glass balloons has been completed, the water is allowed to cool off, and the alkaloid is quickly placed in it. Then the glass balloons are placed in the solution, and filled.

The employment of sublimate cotton, totally neglected in Limousin's process, guarantees for Friedländer's solution an absolute freedom from septic germs, while, on the other hand, the integrity of the alkaloid is strictly preserved.

It now only remains to close the elongated neck of the balloons, which is easily effected by the jet of a flame held near the mouth of the solution-jar. To avoid mistakes, the balloons containing different alkaloids are, besides being labelled, of a different color,—for example, red for morphine, black for atropine, white for cocaine, etc.

These aseptic solutions, combining absolute purity with great preservability, recommend themselves to the practitioner in every land. Their employment will with certainty prevent the great objectionable features of an otherwise equally convenient as efficient mode of medication. It is scarcely saying too much to affirm that Dr. Friedländer's innovation has permanently and satisfactorily solved a problem which has long agitated the professional mind.

#### A CLINICAL STUDY ON ANTIPYRIN.

IF, in spite of the numerous papers on antipyrin previously analyzed by the GAZETTE, we again open our columns to a review of another discussion of the subject, we do so in the appreciation of the especially valuable clinical features distinctive of this recent essay on antipyrin appearing in the *Deutsches Archiv für Klinische Medizin* (April 22, 1886), as the outcome of Dr. Reihlen's careful observations at the Nuremberg City Hospital. We shall discuss *seriatim* the single divisions as made in Reihlen's paper.

#### I. THE CASES TREATED.

Name of affection.	Patients.	Days of treatment.	Grains of antipyrin.
Typhoid fever.....	29	258	16,770
Croupous pneumonia.....	16	34	2,280
Erysipelas of the face.....	11	43	3,450
Scarlet fever.....	1	2	135
Morbus infectiosus?.....	1	2	135
Puerperal fever.....	1	10	425
Intermittent fever.....	1	5	210
Ulcerative endocarditis.....	1	3	180
Tubercular meningitis.....	1	1	120
Tubercular pleuritis.....	1	30	2,295
Pulmonary phthisis.....	7	29	465
Exsudative pleuritis.....	3	5	288
Bronchectasie.....	1	5	225
Gangrene of the lungs.....	1	5	330
Acute articular rheumatism.	10	36	1,635
Pericarditis.....	2	16	1,050
Chronic dysentery.....	1	3	135
Abscess of the ribs.....	1	3	225
	89	490	30,119

In spite of a large clinical material on hand at the hospital, antipyrin, as seen from the table, was but exceptionally given in phthisis and the acute infectious diseases, in accordance with Merkel's principle, followed in the Nuremberg Hospital, which condemns the "à tout cas antipyrin," and calls simply for a temporary reduction of an excessive and a too persistently high temperature.

#### II. ACTION OF ANTIPYRIN ON THE TEMPERATURE.

Among all cases treated by Reihlen there was none in which antipyrin exerted no influence over the temperature.\* Most generally the fall of temperature after doses of antipyrin shows itself within the first hour after the first dose, and ranges between two-tenths of a degree to two degrees and more.† In two observations of May, in which the thermometer was left in the rectum and read every five minutes, the first fall was observed to amount to one-half degree, and to take place after twenty-five minutes. Still, the rapidity and extent of the fall depends so directly upon the resorption of the drug that no generally valid conclusions can be established in this direction. Aside of resorption, dose, and height of the temperature, the action of antipyrin on the depth, duration, and rapidity of the fall, and subsequent rise of temperature, depends upon various other factors, among which Dr. Reih-

\* The only instance recorded in which the drug failed to affect the temperature appears in Alexander's paper, published in the *Breslauer Arztl. Zeitschr.*, 1884, No. 11, concerning a relapse of articular rheumatism.

† For convenience' sake, we have in this paper exceptionally retained the Celsius scale.

len indicates the following as the principal ones :

(a) Age, sex, and constitution of the patient.

(b) Time of administration and other preceding or simultaneous therapeutic interferences.

(c) Mode of distribution of the daily dose.

(d) Nature and stage of the disease.

The younger the individuals and the less vigorous their constitutions are, the greater and prompter is their reaction to antipyrin. It is for this reason that the drug is particularly useful in children's diseases and those marked by profound debility. Thus, in children of two to three years of age, three doses of  $1\frac{1}{2}$  to  $4\frac{1}{2}$  grains produced frequently a complete apyresis, and in case of a strong man, who, by a dysentery of four months' duration, was reduced to a skeleton, the drug lowered the temperature as far as  $35.5^{\circ}$  C. It also matters considerably whether antipyrin is given during the fall or the rise of temperature. If the action of the drug coincides with a spontaneous fall of the temperature, a profound and collapse-like lowering often results, as especially observed during the last febrile days of grave erysipelas, without, however, imperilling in any way the patients. In typhoid fever the drug shows also a greater efficacy when given in the evening.\*

It is much more difficult to stay or repress the beginning, rise, or reascend of temperature after a fall caused by antipyrin. Doses of 15 grains are here quite useless, but after doses of 30 grains a failure was seen in one case only.

The influence of other antipyretic interferences upon the antipyrin action has been repeatedly observed,—thus, in a grave typhoid fever case of a young girl in whom antipyrin and baths employed separately produced but a minute lowering of temperature, the drug given in the evening, after a number of baths during the day, developed an extraordinary action. Even in connection with calomel (7 grains), antipyrin showed a higher efficacy than when employed alone.

As to the distribution of the whole daily dose, all the author's observations confirm Filehne's assertion that the maximum effect of the drug can only be obtained by an hourly successive exhibition.

Nature and stage of the affection exert, as in the case of all other antipyretics, also with

antipyrin, an essential influence over the degree of its action. Of all affections presenting a febrile elevation, those of the tubercular type present the least resistance against the antipyretic action of antipyrin.† This observation has been made so constantly that in certain dubious cases the suspicion of the tubercular element was either aroused or confirmed by an extraordinarily great reaction to antipyrin, the diagnosis being verified later on. Relatively great effects after small doses were also obtained in a case of puerperal fever, while the acute infectious diseases call for much larger doses. In erysipelas of the face,—an affection well known to present a particularly obstinate continuous fever,—75 grains of antipyrin given in three hours rarely succeeded in inducing a complete apyrexia; at the height of the affection at least larger doses were required to accomplish this end. In croupous pneumonia the above dose given in the stated manner produced likewise but a transient fall of temperature, though in two patients of 17 and 19 years of age, a single dose of 30 and 45 grains of antipyrin led to a complete apyrexia lasting for some hours.

The relation of the stage of a disease to the degree of the antipyrin action is shown most evidently in typhoid fever. While in the first stages of the affection—the period of the high continuous fever—doses of 75 grains produced only an apyrexia lasting three to four hours, with a temperature little below normal, the action of the drug could be observed to grow intenser from day to day in the second and third week of the affection. In this stage doses of 60 or 45 grains frequently cause an apyrexia lasting for ten hours, with the thermometer at  $36^{\circ}$  C. and lower.‡ From these observations it will be seen that no definite average figures can be established for the antipyrin action. All that can safely be said is that the drug shows no tendency to an abnormally low decrease of temperature, and that larger doses cannot produce a general lower level than is obtainable by the quantities stated above.

### III. DOSE.

Demme's assertion§ that single doses ex-

† Of the two cases of collapse observed after antipyrin one was that of a robust young man, presenting for twelve hours a temperature of  $36^{\circ}$  C. and a minimum of  $34.5^{\circ}$  C., who succumbed four weeks later to a small tubercular focus of the lungs.

‡ Ziemssen made an identical observation in the hydropathic treatment of typhoid fever.

§ Vide *Fortschritte der Medicin*, Nos. 20, 21.

\* Liebermeister has pointed out the same result regarding quinine.

ceeding 30 grains ought only to be exhibited in hospital practice, where a reliable surveillance is present, is no longer tenable, experience having since shown this limitation to be uncalled for. The following doses are recommended by Reihlen as giving the most satisfactory results :

In croupous pneumonia and typhoid fever in the first stage,—

In patients of 14 to 16 years of age, grs. 22 + 22, or grs. 30 + 15.\*

In patients of 16 to 20 years of age, grs. 30 + 15, or grs. 30 + 30.

In older individuals, grs. 30 + 30 + 15, or grs. 45 + 30.

In the second stage even adults do not require more than grs. 30 + 30, or 30 + 15.

In erysipelas of the face and head,—

In patients between 15 and 20 years of age, grs. 30 + 30, or grs. 30 + 30 + 15.

In adults, grs. 30 + 30 + 15, or grs. 45 + 30.

In pulmonary phthisis, gr. 30, or grs. 30 + 30 + 15.

Wherever these doses are well borne, but do not suffice, they can with impunity be appropriately increased. The largest quantity ever prescribed by Reihlen was (in a case of erysipelas and in another of pneumonia), grs. 45 + 30 + 30.

In children Penzoldt advises to begin with three successive doses of as many decigrammes (grs.  $1\frac{1}{2}$ ) as the child counts years, though in the grave epidemic of measles visiting Nuremberg in 1884 it became evident that these doses could safely be doubled.

All the doses mentioned thus far refer of course to the administration per os, which in both convenience and safety surpasses all other modes of exhibiting antipyrin. Of Reihlen's fifty-six first patients, only one vomited at the first day. If enemata should appear indicated, the doses should at first at least not exceed the quantities as suggested above for the per os administration ; for the subcutaneous employment of course smaller doses suffice.

The assertions made by various authors regarding a gradual weakening of the antipyrin action on account of the system becoming accustomed to the drug could in no instance be verified by Reihlen's observations.

#### IV. SECONDARY EFFECTS OF ANTIPYRIN.

Clinical experience has taught us to look for copious sweats in cases of a quick and

considerable fall of animal temperature, and for chills and rigors in the subsequent reascent, these phenomena being the constant attendants as well of the spontaneous variations of temperature, as in intermittent fever, as in those produced artificially as by kairin. The reason that kairin never became a popular drug and was soon displaced by antipyrin is to be found in the fact that the reduction of temperature produced by kairin was invariably attended by chills and rigors, symptoms scarcely ever observed after the use of antipyrin. This differential behavior of the two drugs refers to the comparative rapidity of their action, kairin accomplishing both fall and reascent of a certain number of degrees in half the time required by antipyrin.

Slight chills during the reascent of temperature after the use of antipyrin were observed in two instances only (cases of typhoid fever and erysipelas), while sweating after the fall of temperature was a constant phenomenon. The quantity of perspiration, though usually considerable, appeared never to create any inconvenience to the patients.

Vomiting has been repeatedly observed during the period of the greatest fall of temperature, or in the beginning of the reascent. In a typhoid fever patient, a robust woman of 35 years of age, who received antipyrin per anum, vomiting occurred every afternoon for eleven days, and only ceased after prolonged baths were substituted for antipyrin ; the reduction of temperature produced by the bath not being nearly so great as that caused by antipyrin. Reihlen believes the vomiting in this instance to be primarily the result of the great variation of temperature and to refer only indirectly to the drug itself.

#### V. ACTION OF ANTIPYRIN ON THE HEART.

Antipyrin affects the heart almost equally constantly as the temperature and the functions of the skin.

The frequency of the pulse is usually found to be parallel with the variations of temperature,—i.e., to fall with the reduction of temperature and to rise with the reascent of the latter. In cases of general debility only, such as marasmus, phthisis, and heart-disease, this synchronic behavior of pulse and temperature was interfered with.

The action of antipyrin upon the quality of the pulse invites our especial interest. Quite in accordance with the previous observations of Noorden,† Cahn, and Demme, Reihlen

\* The formulæ indicate doses of hourly succession.

† *Berl. Klinische Wochenschrift*, 1884, No. 32.

noted usually an increase in the tension of the vascular walls and the blood-pressure after the exhibition of antipyrin. Still, the increase in the tension of blood-vessel walls did not always proceed *pari passu* with the temperature-variations, and differed in the same individual on various days. Again, in several instances the pulse appeared to have decreased in tension, and called for the suspension of the remedy or for the simultaneous administration of stimulants. In the non-febrile cases treated, all of which belonged to the rheumatic type, the pulse appeared unaltered, both regarding frequency and pressure. In two of these cases, however, temporary palpitation of the heart set in, and, together with other observations, such as the occurrence of sweating in all non-febrile cases, induces Reihlen to ascribe to antipyrin a direct action on the vascular system independent of its action on the temperature.

The respiratory functions remained unaltered after antipyrin in the cases of pneumonia observed.

The action of the drug on the spleen, as reported by Müller, of Würzburg, could not be confirmed.

Cahn reports the case of a phthisical woman in whom pregnancy was not interfered with by a drachm dose of antipyrin. If this observation, which at present is the only one of its kind recorded, should be proven to be the rule, this property of antipyrin would enhance its value in view of the dreaded emmenagogic influence of quinine and salicylate of sodium.

#### VI. MODE OF ADMINISTRATION.

Antipyrin in a watery solution is quickly absorbed from the intestinal tract and the interstitial connective tissue. Internally, it is best given in wine or in wafers to disguise its taste, which is bitter, like quinine, but soon disappears. Repugnance, and even vomiting, are not rarely noted to follow a prolonged ingestion of the drug, no matter in what form. In such cases it is well to constantly change the mode of administration between wine, wafers, and the enematous form. For the latter Reihlen uses rather concentrated solutions, and never saw any irritating effects upon the intestines, though he greatly questions the promptness and reliability of this form of medication.\*

\* The method advocated by Rank, viz., hypodermic injections of watery solutions, prepared warm, was tried once, but soon abandoned on account of the serious inflammatory reaction it produced.

#### VII. INFLUENCE OF ANTIPYRIN ON THE GENERAL STATE OF THE ECONOMY.

Of all authors who have discussed the question of the influence of antipyrin upon the general condition of the system, Penzoldt alone gives a positively favorable opinion. We quote his words from his essay in the *Berliner Klinische Wochenschrift*, 1884, No. 30:

"The general state of health of children after taking antipyrin, no matter whether the antipyretic action was complete or incomplete, was in the great majority of cases decidedly improved: they appeared livelier, slept better, and sometimes coughed less." The other observers have generally contented themselves with emphasizing the absence of untoward sequelæ, chiefly of collapse.† May, on the other hand, mentions from a large material on hand only three cases, with an improvement of the general health. Alexander (*J. c.*) can furnish but one instance of a general improvement following after the use of the drug.

In opposition to these isolated examples of a favorable impression of antipyrin upon the economy, we have the following unambiguous conclusion of Ernst, of Zürich, representing his experience with the drug in the great epidemic of typhoid fever in 1884: "Our epidemic has again definitely proven how little sometimes is accomplished by a mere apyrexia, delirium and other symptoms of a profound general infection taking their course independently of it."

Reihlen could not observe, aside from exceptional cases and the euphoria subsequent to sweating, that antipyrin exerted any material influence over the general state of the patients.

It is interesting to note that Reihlen's and Ernst's pertinent observations are in a singular contrast with the doctrine of Liebermeister, who regards "the increase of animal temperature not only as the pathognomonic symptom of fever, but also as the direct cause of the principal and characteristic features of fever."

#### VIII. NATURE AND VALUE OF THE ANTIPYRIN ACTION.

It is universally conceded that antipyrin, though able to reduce and shorten the temperature elevation of the paroxysms of malaria, exerts no influence whatever upon the affection itself. In acute articular rheumatism,

† The Nuremberg physicians who employed the drug extensively during the great epidemic of measles in 1884, speak very favorably of its general influence.

however, authors like Demme, Lenharz, and Guttman agree that the drug, like the preparations of salicylic acid, evinces a certain specific influence over the pathological process.\* Reihlen himself observed six cases of rheumatism in which—the preparations of salicylic acid having proven useless or being contraindicated—antipyrin showed rather gratifying results. Still, Reihlen appears to have good reasons to put no high estimate on the virtues of antipyrin in this direction. In pneumonia and typhoid fever the effects of antipyrin, as hitherto recorded, are likewise little encouraging. In the latter affection, Dr. Kurz, of Florence, is possibly the only clinician who claims any great value for the drug. Reihlen's own observations in typhoid fever showed that antipyrin affected the process itself in no way whatever.

We thus are obliged to conclude that antipyrin in no affection has any specific or even direct influence upon the morbid process, and that its sole value rests in the check it places upon the dangers of an excessive febrile temperature. And bearing in mind the consequences of an overheating of the blood, an increased albuminous destruction,† and the fatty degeneration of tissue, the value of antipyrin will nevertheless be not underrated. The interesting questions pertaining to the nature of the physiological action of the drug

have hitherto been but imperfectly answered. Demme claims that antipyrin is a general protoplasm poison, producing first an increase and later a reduction of the excitability of heart and nerve-centres. In frogs and rabbits a subcutaneous injection causes first a heightened and then a lowered arterial pressure, first convulsions and later paralysis of the muscles of the extremities and pupils, death ensuing through cardiac arrest. It is uncertain how the antipyretic effects are precisely brought about. Noorden excludes the assumption of an increased discharge of heat, for he found that a suppression of the sweat through atropine had no effect upon the amount of the same.

IX. ANTIPYRIN AND THE OLDER ANTIPYRETIC METHODS.

Nearly all authors who wrote about antipyrin felt induced to compare the new remedy with the old and well-tested ones, especially with quinine. Their final conclusions, though invariably favorable to antipyrin, refer, however, more to the absence of undesirable secondary effects and the promptness of the antipyretic action than to the relative degree of the latter. Guttman alone has made comparative researches in this direction, and asserts that 30 grains of quinine have as great and constant an action as 60 to 75 grains of antipyrin.

The following table, compiled by Reihlen, represents a comparative review of average antipyretic effects of various methods, as drawn from his own observations as well as those of other authors.

Average Value of Effect of Antipyretic Methods in Typhoid Fever.

AGENT.	Dose.	Remarks.	Average degree of temperature-fall in degrees (C.).	Average duration of temperature-fall in hours.
1. Quinine*.....	15 to 30 grs....	Given in the morning and evening.	1.6° to (3.0°) 0.7°.	4 to 20 hours.
2. Gradually cooled baths† (from 27° to 16°); duration, 30 to 40 minutes	.....	Adults: { 2d week, { light cases. { 3d "    { grave cases.	1.8° to 2.0°..... 1.8° to 1.9°..... 1.9° to 2.4°.....	4.2 to 9.5 hours. 5.7 to 6.0 " 6.4 to 9.7 "
3. Cold baths‡ (temp. 15° to 20°); duration, 15 minutes.	.....	Light and grave cases un-separated.	2.3°.....	About three hours after bath return to original temperature.
4. Salicylate of sodium. §	90 to 120 grs. { 60 grs.....	Light and grave cases un-separated.	2.0°..... 2.0°.....	Longer than after quinine. Shorter " " "

*Average Value of Effect of Antipyretic Methods in Typhoid Fever.—Continued.*

AGENT.	Dose.	Remarks.	Average degree of temperature-fall in degrees (C.).	Average duration of temperature-fall in hours.
5. Prolonged lukewarm baths* (temp. 25° to 27°); duration, 3-6 hours.		Medium cases..... Grave cases.....	1.5 to 2.5°..... 1.0°.....	About one hour after bath return to original temperature.
6. Kairin.....	Various.....		Depth of fall usually greater than after antipyrin.	Duration of fall usually shorter than after antipyrin.
7. Antipyrin.....	30 + 30 to 30 + 30 + 30 gm.	Second week of medium cases.	2 to 3° (4.5°)....	Temp. below { 39.0, about 9 to 12 hrs. 38.5, " 6 " 37.8, " 4 "

\* Zwiesler, "Prolonged Lukewarm Baths in Typhoid Fever." Nuremberg, 1882.

As seen from the above table, antipyrin surpasses all known antipyretic agents as far as the duration of the temperature reduction is concerned. Nevertheless, the principal virtue of the remedy does not reside in the degree of its action, but in the promptness and certainty of the latter and also in its absolute harmlessness. Compared with the nervous excitation after quinine, the tinnitus aurium after salicylate of sodium, the chills after baths, and the rigors after kairin, the occasionally noted vomiting after antipyrin ought to be regarded as of little consequence.

Antipyrin has, as could be expected, already displaced kairin from the field of practice, and will do likewise with salicylate of sodium wherever the latter, as in typhoid fever, is only given for the sake of its antifebrile effects. It cannot, however, be expected to replace quinine, or to render the baths superfluous, for in either case the medicinal virtues are not limited to a mere antifebrile action.

## Reports on Therapeutic Progress.

### *TENDON-JERK AND MUSCLE-JERK IN DISEASE, ESPECIALLY WITH REFERENCE TO POSTERIOR SCLEROSIS OF THE SPINAL CORD.*

At the first meeting of the Association of American Physicians, held June 17 and 18 last, in Washington, Dr. S. WEIR MITCHELL, of Philadelphia, and Dr. MORRIS J. LEWIS, of Philadelphia, read a paper with the above title (*Boston Med. and Surg. Journ.*, June 24, 1886).

The investigators believed that, by their work, they had increased the knowledge of

the symptomatology of this affection. It was stated that while a muscle or a nerve may be excited by both electrical and mechanical irritation, the former is to be regarded as a ruder agent than mechanical stimulus. In some cases electricity is inapplicable beyond a certain extent. It was held that the knee phenomenon was a direct muscular response, and not due to reflex action. The most delicate test for determining the condition of the muscle is by striking the stretched tendon. This can be done in various situations, as at the knee, ankle, elbow, and jaw. Every distinct muscular exertion, such as winking, if accurately timed, exaggerates these phenomena. To demonstrate this, the patient should lie down with the knee slightly bent. At the time that the tendon is tapped, or just before, the patient is directed to wink, and it will be noticed that the jerk is much increased. This is more beautifully shown in the act of phonation, the patient being directed to count strongly, bringing the whole chest into play at the time the test is applied. A decided sensation, such as heat, cold, or an injury, will increase the responsive power of the muscle or tendon which has been struck. Both the tendon- and the muscle-jerk are reinforced by irritation of distant parts. This reinforcement disappears when the muscles are cut off from the spinal centres.

A blow on the muscle causes the muscle-jerk to extend up and down, but not transversely. In some cases of disease this jerk is irregular. In addition to this contraction, the muscles may form a little eminence or mound, which disappears slowly. Late in ataxia this is unusually well marked. It is also observable in some healthy muscles.

The phenomenon of reinforcement was at-

tributed to an increase of tone in the muscle as a result of the distant irritation.

A tabular statement was then presented giving the results of observation in twenty-three cases of locomotor ataxia. In this table the various symptoms and signs presented were represented by signs. In this way the history of each case could be seen at a glance.

In selecting a decisive symptom by which to arrange the cases into classes, station, or the ability to stand, was selected. This can be accurately estimated by having the wall back of the patient ruled in inches. The examiner takes his place in front of the patient, and directs the patient to keep his eye on a particular spot above the head of the observer. It is then noted how much he varies laterally with his eyes open. He is then turned so that the anterior-posterior sway may be noted. The examination is then made while the patient has his eyes closed. Numerous examinations made by Dr. Guy Hinsdale show that the normal man does not sway over one-half inch laterally, and not over three-fourths of an inch in the anterior-posterior direction. The normal man sways forward first, and first to the right. When the sway is more than three-fourths of an inch in the lateral direction, or more than one inch in the antero-posterior direction, the case should be looked upon with suspicion as indicating that the general health is disturbed, or that there is some disease interfering with the maintenance of the equilibrium. The cases were divided into four classes: 1, those in which station was normal; 2, those in which it was slightly impaired; 3, those in which it was greatly impaired; and, 4, the paralytic cases. In the cases examined, the knee- and ankle-jerks, and their reinforcement, were absent at the time when the cases came under observation. The changes in the arm-jerk seem to advance in the same way as the leg-jerks, although they come on later. In the paralytic stage the muscle-jerk is increased, although the reinforcement is absent. In the first stage of locomotor ataxia the tendon-jerk is diminished or absent, while the reinforcement is fair. In the subsequent stages both the tendon-jerk and its reinforcement are absent. The muscle-jerk and its reinforcement continue normal through the first two stages. In the third stage, while the muscle-jerk is normal, the reinforcement is absent. In the fourth stage the muscle-jerk is increased, while the reinforcement is absent. In the fifth stage the muscle-jerk is diminished, and the reinforcement is absent. In the sixth stage both the muscular jerk and the rein-

forcement are absent. The increase of the muscle-jerk late in the disease may be due to some irritative changes in the muscle, but this has not been positively determined.

In regard to associated movements. In a certain proportion of cases, if the patient is directed to shut his right hand, the left hand will also shut to a certain extent, and if the patient is sitting down, the leg may be drawn up. This condition has become more marked as the ataxic condition has increased.

Another symptom referred to, and which was considered a new symptom, was prominence of the eyeballs. While the condition is not as marked as in exophthalmic goitre, it is sufficiently distinct to be apparent if attention has been called to the matter.

#### QUEBRACHO.

MM. ELOY and HUCHARD, in an article on "The Bark and Active Principles of Quebracho Blanco," published in the *Archives de Physiologie et Pathologie*, April 1, 1886, arrive at the following conclusions: The bark of quebracho blanco furnishes four active substances, all with different symbols and physiological and toxic properties. The active principles of quebracho modify but little the general sensibility of mammalia (guinea-pigs, rabbits, and dogs). Quebrachine, hypoquebrachine, aspidospermine, aspidospermatine, pure, do not influence general sensibility, but the residual products after their extraction apparently do. In some experiments, the phrenic nerve was more susceptible to galvanic stimulation after aspidospermine had been administered than after quebrachine.

Motility is affected in various ways. Strong doses of aspidospermine cause convulsions; small doses, fits of trembling; very large doses, rapid paralysis. One of the most remarkable phenomena observed in the animals experimented on is hoarseness, sometimes aphonia, especially in guinea-pigs; this may be attributed to paralysis of the extensor muscles of the vocal cord. Quebrachine causes muscular paralysis both more rapidly and more evidently; hypoquebrachine and aspidospermatine are analogous in action to quebrachine, but less evidently so than aspidospermine. The residual products provoke thorough and rapid paralysis. Four or five minutes after a hypodermic injection, paralysis attacks the extremities of the limbs, rapidly affects them throughout, and is alternate with tonic convulsions. Circulation is not

modified either by the residual products or by hypoquebrachine or quebrachine, but the heart-beats became slower under the influence of aspidospermine, and quicker after injections of aspidospermatine.

It is important to control previous researches concerning the action of quebracho on respiration, its bark being recommended for different kinds of dyspnoea. Quebrachine does not alter either the rhythm or the depth of the respiratory movements, neither do the residual products of aspidospermatine; hypoquebrachine slightly modifies them. Aspidospermine, on the contrary, increases the amplitude of respiratory movements in the proportion of 1 to 5 in eight or fifteen minutes; then, a moment afterwards, the rhythm is increased, and continues so during two, three, and even four hours; it is not like the increase in amplitude. If the dose be increased or eliminated, arrhythmia occurs, and the depth and amplitude of the movements are lessened. Aspidospermine has a greater influence on the frequency of costal respiration than on abdominal. It is therefore of all the active principles of quebracho the greatest modifier of the respiratory movements. All the active principles of quebracho modify the temperature. The residual products raise it, but this seems to be due to asphyxiation. The aspidospermine which is currently sold lowers the temperature from 2 to 3 degrees (Centigrade) in a space of from thirty to forty minutes; aspidospermatine from 3 to 6 degrees in nineteen minutes; hypoquebrachine the same.

Of all these substances, quebrachine is the most antithermic. Venous blood is black when the animal is asphyxiated by the influence of residual products, reddish or red under the influence of quebrachine, hypoquebrachine, and aspidospermatine, that is to say, the substances that lower the temperature. This coloration is comparable to that observed in animals which die whilst the interchange of gases is arrested. These substances cause excessive secretion of the kidney, and the intestinal and salivary glands; hypoquebrachine and aspidospermine produce diarrhoea and diuresis; aspidospermine increases salivary secretion in dogs, urinary secretion in guinea-pigs and rabbits. The residual products have the same action on the intestinal glands and on the kidneys. All these substances can cause death. The residual substances are the most toxic; next in order are quebrachine, aspidospermatine, and, lastly, aspidospermine. Death results

either from asphyxia or from paralysis of the muscles of respiration, when the doses are considerable; more slowly from arrested interchange of gases, when the doses are smaller and elimination is only partially effected. By administering suitable doses of these principles, the residual substances excepted, useful therapeutic agents may be obtained. It must be remembered that quebracho is not an inert substance; if it do not realize all that enthusiasts assert, it nevertheless has certain merits. These researches were undertaken by MM. Eloy and Huchard to verify what has been asserted by previous investigators, also to study the action of each active principle of the bark. MM. Eloy and Huchard are engaged in further researches on quebracho, which will be shortly published.—*London Medical Record*, June 15, 1886.

#### ON QUILLAIC ACID.

From ROBERT's remarks on quillaic acid made at the Strasburg meeting of physicians and naturalists last year, as appearing in *Heitler's Centralblatt*, April, 1886, p. 183, we abstract the following *résumé*: The saponine of the market, a mixture of various organic and inorganic substances, contains but little pure saponine, and owes its poisonous properties to quillaic acid and sapotoxine. The former, which can be prepared from the quillaia bark much easier, is itself and in all its combinations extraordinarily toxic, 0.5 mg. ( $\frac{1}{2000}$  gr.) of the acid pro kg. (2 lbs.) of bodily weight introduced directly into the blood killing a dog or a cat, while 2.0 grammes (30 grs.) ingested per os are borne with impunity. The acid affects particularly the muscular apparatus, and in its effects resembles polygala senega. As pronounced by Schmiedeberg, the quillaic acid belongs to the protoplasma poisons.

#### TREATMENT OF ASPHYXIA OF THE NEW-BORN.

DR. L. N. SHARP, of Minneapolis, Minn., writes to the *Medical Record*, July 3, 1886, that the perusal of an abstract with the above title has led him to describe a method accidentally discovered many years ago by himself. He was trying to resuscitate an asphyxiated new-born child, but did not succeed, and the pulsation ceased in the cord. "I cut the cord, and continued Marshall Hall's method till I became convinced the child was dead. So many years have now passed that I cannot

speak of the condition of the heart, but am under the impression I continued my efforts till the beat of the heart could not be heard. Then I asked for a cloth in which to wrap the body, and took the child in my hands, holding the feet in an elevated position with my right hand, while the back and shoulders of the child, in a depending position, lay upon my left hand. The nurse was tardy in bringing me the cloth, and while I was holding the babe it gasped. I laid it down on the bed, and again commenced Marshall Hall's method for resuscitation, but no results; I became convinced again that the child was dead. Taking it in my hands again in the manner above described, I asked for a cloth, and as before had to wait a little, and while waiting the child gasped. The thought came to me at once that the child gasped because the force of gravity carried the blood to the brain, and the lack of this was why the child was dying. I held the child in the same position till gasp after gasp brought respiration and circulation to a normal condition. The child lived. And many, many times since have I resuscitated children which I think would not have lived had I used the ordinary methods."

#### DIFFERENTIAL TOXICOLOGICAL BEHAVIOR OF GELSEMININE AND STRYCHNINE.

The possibility of mistaking a case of strychnine-poisoning with criminal intent for an accidental intoxication caused by a prescribed preparation of gelsemium recommended to our notice RAIMONDI's pertinent comparative investigations as set forth in the *Ann. di Chim. Med.*, Sett., 1885. If it is possible to recover enough of the poison to enable us to experiment with it on warm-blooded animals, the nature of the poison is readily established. If, however, the scantiness of the substance in question allows only experiments on frogs, the following differential features must be our guide:

1. In gelsemium-poisoning the motor paralysis has a central cause, which does not apply to strychnine.

2. The effects of strychnine manifest themselves with equal intensity over the whole body, while in gelsemium-poisoning the posterior extremities show the clonic-tonic convulsions more distinctly than the anterior ones.

3. Immediately or shortly after one strychnine paroxysm, a second may follow; in gel-

semium-poisoning considerable time usually elapses between the single paroxysms.

4. The stage of tetanus from strychnine may last several days, that of gelsemium rarely exceeds an hour.

5. In chemical respects the two drugs present also some characteristic differences, which, under the name of Schwarz's differential reactions, are detailed in Raimondi's paper.

#### COCAINE IN LAVAGE OF THE STOMACH.

DR. CHARLES N. DIXON JONES, of Brooklyn, writes to the *New York Medical Record*, July 3, 1886, as follows: "Gastric lavage is rapidly becoming our most reliable treatment in chronic dyspepsia and gastritis. In order to avoid some of the disagreeable features attending this operation, I have resorted to the following expedient: About fifteen minutes before commencing the operation the patient is allowed to hold in his mouth a piece of absorbent cotton saturated with a four per cent. solution of hydrochlorate of cocaine; in a few minutes the palate and fauces are painted with the same solution. The stomach-tube is lubricated with a mixture of olive oil, oil of wintergreen, and cocaine, after which it may be introduced and the stomach irrigated without that disagreeable vomiting of the tube and efforts at gagging which frequently attend the operation. I have adopted this method in some of the most trying and difficult cases, and always with the most happy result."

#### OBSERVATIONS ON THALLIN IN TYPHOID FEVER AND PNEUMONIA.

DR. KARST, of the Russian navy, communicates to the *Wratsch*, No. 2, 1886, a number of interesting observations made with thallin in twelve cases of typhoid fever and croupous pneumonia. The average dose employed was 3 grains. He observed a reduction of the temperature in fifty-eight instances amounting to 2-3° C., in twenty-seven 1-2° C., in eighteen 0-1° C., and in fourteen 3-4° C., while in five instances the temperature was noted to rise 1° C. The greatest fall usually took place about an hour after ingestion of the drug, and lasted for two to three hours. Profuse perspiration was observed fifty-eight times, slight perspiration forty times. Rigors setting in during the fall of temperature were observed twenty-five times, but could usually be aborted by a new dose of thallin. Pulse and respiration became slower under the

influence of the drug. After the exhibition of large doses of thallin the urine assumed a dark brown coloration, and inclined towards a rapid decomposition. Noticing an invariable decrease in the quantity of urine voided during the days of the thallin medication, Karst concludes that the oxidation processes are checked by the drug and not, as Magliano assumed, favored. Two healthy individuals who took 60 grains of thallin during three days complained of slight headache and cardialgia; their pulse and respiration were slowed, and their urine presented a dark green color.

#### LARGE DOSES OF IODIDES AND BROMIDES IN MENINGITIS.

DR. J. F. STEVENS, of Shabbona, Ill., reports in the *Medical Record*, July 3, 1886, a case of meningitis occurring in an infant 8 months of age. The disease when the child was first seen had so far advanced that parallelism of the eyes was lost, strabismus ensuing. The little patient was evidently failing rapidly, was unconscious, with head retracted somewhat. This condition had come on slowly. There had been no convulsions or convulsive movements. The bowels were extremely constipated, with the abdomen somewhat retracted. The respiration was irregular, and pulse somewhat quickened. A powder containing 5 grains of calomel was given, and was followed in one hour by a full dose of castor oil. Blisters were placed behind the ears and mustard to the feet, taking care to cover the soles thoroughly, and an ice-bag was placed at the head. In about one hour the patient aroused somewhat, and in an hour and a half, by which time the bowels moved, cried out several times.

R Sodii brom.,  $\mathfrak{z}$ ss;  
Aqæ,  
Syr. simplex, aa q.s. ad  $\mathfrak{z}$ iii.  
Sig.—One full teaspoonful every hour.

10 grains of bromide of sodium were given every hour, and  $\frac{1}{2}$  grain of iodide of potassium was given every second hour. At the end of twenty-four hours the latter was given only once in three hours. The bromide of sodium was given in doses of gr. x every hour, continuously, for four days. Under this treatment the condition of the patient slowly improved, but any attempt at reduction of the dose was sure to be followed by bad symptoms.

At the end of four days the bromide was

given once in two hours; from this to once in four hours, and then three times a day. The iodide was persisted in until symptoms of iodism manifested themselves, when the medicine was gradually withdrawn. During all this time the ice-cap, filled now with simply cold water, was used. The bowels were kept open with the oil.

Some fourteen days after the case was first seen small abscesses appeared on the scalp, which would discharge about a teaspoonful of pus when opened. These continued until ten were formed. On the eighteenth day the treatment was changed, citrate of iron and ammonium in cod-liver oil three times a day. Small doses of brandy were also given from time to time. The patient is now steadily improving, and bids fair to recover. Both ears have discharged fetid pus freely.

There was no history of syphilitic trouble in the parents, though there had been tuberculosis in a preceding generation.

#### ON PEPTONE SOUP-POWDER.

We have in a previous issue of the *GAZETTE* recommended the peptone soup of DR. JAWORSKI (of Carlsbad) as a dietetic article of considerable value for the sick-room. Still, the inconvenience connected with the daily fresh preparation of the soup was a very patent drawback to its universal adoption. As we learn from the *Zeitschrift f. Therapie* (No. 29, 1885) and the *Deutsche Medizinische Zeitung* (No. 23, 1886), Dr. Jaworski has succeeded in removing this disadvantage of the otherwise very valuable preparation by changing it from the liquid to the solid form. The peptone soup-powder as prepared by the apothecary May, of Berlin, after the instruction of Jaworski, not only fully represents the advantages of the peptone soup, but also widens the sphere of its applicability. The powder, prepared also in form of pastilles or lozenges, can be well preserved and employed like medicines in definite doses and intervals. As about three ounces of the powder are requisite for the daily nutrition of patients, it is advisable to mix about one-half of this quantity with the other articles of diet allowed. Jaworski confines the clinical employment of the peptone soup-powder to the following indications:

1. All cases which call for a peptone alimentation per os or per anum.
2. In a required sur-alimentation the peptone soup-powder can advantageously replace

Debove's meat-powder, which it surpasses in resorbability and digestive efficacy.

3. In all cases of forced nutrition, such as in idiotic patients.

#### THE THERAPEUTIC VALUE OF THAPSIA PLASTER.

The resin which forms the basis of this plaster is obtained from the root of the thapsia garganica, an umbelliferous plant growing in Southern Europe and Northern Africa, bordering on the Mediterranean Sea. Although employed internally as an emetic and purge and as a counter-irritant for rheumatic pains by Galen and other old writers, its use seems to have declined until 1868, when it was revived in France. As used in this country, the plaster is composed of seven per cent. of the resin, combined with yellow wax, colophony, and turpentine. There seems to be some difference of opinion as to its value, but it appears to be but little known by the profession in this country. The French plaster occurs in the form of rolls and cylinders, of an orange-yellow color, which is very cleanly in its application, leaving but little residue on the surface when removed. This plaster has been subjected to study by Dr. JAMES K. CROOK (*New York Med. Journ.*, July 10, 1886), who has employed it in several cases of neuralgia and muscular pain. According to Dr. Crook, the heat of the body and hand is sufficient to make it adhere. A vigorous friction of the surface with a spirituous solution before laying on the plaster will greatly augment its activity. In a period varying from five to ten hours after its application considerable itching of the part supervenes, and, if the edge of the plaster is everted, the skin beneath will be found of a uniformly scarlet hue. It should be removed as soon as the irritation becomes sufficient to render it annoying. In many cases he has found that it could be well borne for twenty-four hours; but, as will be seen, it is not always safe to advise so long an application. Within from twenty-four to thirty-six hours it will be found that the area of efflorescence has extended considerably beyond the limits of the plaster, and that the eruption is assuming the form of a punctate or miliary rash, thickly scattered over the surface. In some cases the centres of the papules are occupied by minute vesicles, which may proceed to pustulation. The local redness and irritation continue for about four days, and then begin to decline. If vesicles have been formed, they dry up and dis-

appear speedily, though a purplish-red discoloration of the skin may persist for several weeks. The eruption is not unlike that produced by croton oil; but Dr. Crook has never observed umbilication of the thapsia vesicles, nor in any case have cicatrices remained after their disappearance.

There are two principal objections to the use of the thapsia plaster: 1. The remarkable tendency of the eruption to spread, making it difficult to confine the sphere of its action within desired limits. 2. The occasional severe and painful character of its local action. These drawbacks may be partially overcome by prescribing a piece of the plaster much smaller than the surface desired to be acted upon, and, if it is a first application, by counselling the patient to remove it within six hours. Of course, if the plaster is being used on a patient for the second or third time, and he has been found to possess no idiosyncrasy to its action, it may be allowed to remain much longer. It is his belief that a tolerance is acquired for thapsia after repeated use. If the irritation produced by the plaster is unusually severe, an inunction of olive oil, or glycerin and rose-water, or simply pulverized starch, will usually give relief. Patients should be cautioned to wash the hands after handling the plaster, as the resin may be conveyed to other parts in this way. He has several times observed an erythema of the face produced by it, and in one case a mild conjunctivitis was developed.

From the cases in which Dr. Crook has employed it, he thinks that this plaster has special value in muscular and rheumatic pains of long standing in which other remedies have failed to give relief. He has had but little success with it in acute troubles of this nature. It has also seemed to him to be a useful application to the chest in the irritation and painful coughs of phthisis and chronic bronchitis, especially when accompanied by difficulty of breathing. In cases of simple cardiac palpitation of neurotic origin, the importance of which is often enhanced by the imagination of the patient, a small piece of the plaster applied to the *opposite* side of the chest will often act advantageously by withdrawing the patient's attention from the heart. On theoretical grounds, the plaster should act beneficially in promoting the absorption of pleuritic fluid and in favoring resolution in phthisis. Dr. Porter has employed the plaster for a number of years past, and has extended its application to a much wider field. He states that he holds it in high estimation. The irri-

tating properties of thapsia rather disqualify it for use in children.

Regarding its mode of action, thapsia may be classed among the most vigorous counter-irritants or derivatives. Its influence is undoubtedly chiefly exerted by the active determination of blood which it excites from the deeper structures to the surface. Its effects may also be partially produced, in common with those of other counter-irritants, through the trophic nerves, the *methodus medendi* of which does not seem to be fully understood as yet.

#### A CONTRAINDICATION OF PARALDEHYDE.

It has been asserted that paraldehyde does not give rise to any unfavorable secondary symptoms, and that there is no known contraindication to its administration. In the *Neurologisches Centralblatt*, No. 31, 1886, we find, however, a little note by Dr. SOMMER, of Allenberg, which renders the correctness of these views doubtful. A patient, 18 years of age, who for six successive days had taken daily doses of one drachm of paraldehyde, showed on the seventh day, a few minutes after having drunk half a bottle of beer, a deep scarlet injection of the skin, covering almost the entire head, neck, back, posterior surfaces of the lower extremities, and partially the chest, abdomen, and upper extremities. This peculiar phenomenon lasted half an hour. For the sake of an experiment Sommer gave the patient on the next evening another dose of paraldehyde, followed by a small quantity of alcohol on the next morning. The same vascular injection having appeared again, Sommer concluded that paraldehyde ought not to be given to patients presenting atheromatous defects, and should at least not be employed in connection with alcoholic liquids. Only one other observer, Eickholdt, has previously observed similar interferences of the circulation following after the employment of paraldehyde. He noted the occurrence of cerebral congestions and of vaso-paralytic symptoms after the prolonged use of this drug.

#### INTUBATION OF THE LARYNX.

Intubation of the larynx is attracting a great deal of attention at present as a substitute for tracheotomy, and we have in several issues alluded to the results obtained by this mode of procedure in the hands of different

physicians since it has been introduced by Dr. O'Dwyer, of New York. It may not be out of place to again give the methods employed and this procedure as recommended by Dr. INGALLS :

The child should be wrapped in a sheet or shawl, which will pinion the arms, and then held upright in the nurse's lap ; an assistant holds the child's head. The gag is then introduced between the jaws, and opened as wide as need be, but not with great force. Dr. O'Dwyer says that it is unnecessary to use the gag with infants who have not back teeth. The physician, sitting in front of the patient, passes his left index finger over the base of the tongue and down behind the epiglottis, and with it guides the end of the tube into the glottis. The handle of the applicator should be held near the child's sternum until the end of the tube has reached the pharyngeal wall, when the handle is rapidly elevated, and tube directed downward and forward along the index finger into the larynx. This will not be found difficult, but the infant's epiglottis is so small and flaccid, that the operator may not be able to recognize it, though he will have no difficulty in recognizing the larynx as a whole, which, except that it is slightly irregular, feels much like the end of one's little finger. The operator should not expect to detect the opening of the glottis, but must be guided by his anatomical knowledge to pass the tube into the centre of the larynx. Unless he is careful to carry the handle of his instrument high, and thus bring the tube as far forward towards the base of the tongue as possible, the tube will pass into the œsophagus. While it is desirable to accomplish this portion of the operation as quickly as possible, it should not be done with too great haste. Ten or twenty seconds, which is a long time for this portion of the operation, may be taken without danger. If the tube is not then introduced, it should be removed for a minute or two, to allow the child to breathe, and then the operation may be repeated ; but if the tube seems to be in the proper position, whether the operator is certain of it or not, the slide upon the handle should be crowded forward, so as to disengage the obturator, which is then withdrawn. Some cough will occur at once, and, if the tube has not been inserted into the larynx, or if it has not been passed down so that the rim rests on the vocal cords, it is likely to be expelled, and may be seen or felt in the back part of the mouth. If the tube has been properly inserted, respiration will become

easier, and after a few minutes the operator cuts one end of the silk thread, passes his finger behind the epiglottis, and holds the tube while the thread is withdrawn.

DR. DAVIDSON (*Buffalo Med. and Surg. Journ.*, July, 1886) has also employed this procedure, and he agrees with Dr. Waxham, who has had by far the largest number of operations up to this time, as to the following advantages which intubation possesses over tracheotomy :

1. No opposition is met with on the part of parents. Quite a contrast with the difficulty which we usually meet with in obtaining the consent to tracheotomy.

2. It relieves the urgent dyspnoea as promptly and as effectually as tracheotomy, and, if the child dies, there is no regret that the operation was performed, and no discredit attached to the physician.

3. There is less irritation from the laryngeal tube than from the tracheal canula. As the tube is considerably smaller than the trachea, it does not press upon it firmly at any portion, excepting at the chink of the glottis.

4. Expectoration occurs more readily than through the tracheal tube.

5. As the tube terminates in the throat, the air that enters the lungs is warm and moist from its course through the upper air-passages, and there is less danger of pneumonia.

6. It is a bloodless operation.

7. It is more quickly performed, and with less danger.

8. There is no open wound, which may be the source of constitutional infection.

9. Convalescence is more rapid, and there is no ghastly wound to heal by slow granulations.

10. The patient does not require the unremitting care of the surgeon as in tracheotomy.

11. It as yet seems to be a more successful method of treating croup, either diphtheritic or membranous, than tracheotomy.

There are, however, certain disadvantages connected with it, and these are formulated by Dr. Davidson as follows :

1. The difficulty of inserting the tube. This, though admitted, is certainly less than tracheotomy.

2. That the tube may become blocked with mucus or membrane. The recorded experience in thirty-seven cases would indicate that this does not occur, because—and this is one of the marked advantages of tubage over tracheotomy—the patient has the ability to compress the air in the lungs and expel it

with an explosive force ; in other words, to cough,—thereby clearing the tube.

3. That the tube may slip through into the trachea. If too small a tube is used, this may happen, but from the length of the tube, it cannot sink out of reach, and may be removed by the mouth or by tracheotomy.

4. That the child cannot swallow well. This is true only of fluids, and it is necessary to avoid giving liquids by the mouth. A few drops will trickle into the trachea and cause violent coughing, and this irritation will often lead to pneumonia. Dr. Waxham has devised a feeding-bottle for young infants, and it may be necessary to use a small-sized œsophageal tube in some cases.

5. The canula may be coughed out in the absence of the physician, and death ensue before he can be summoned to reintroduce it. This danger is not nearly so great as that which attends the wearing of the tracheal tube.

It seems as yet too soon to pronounce absolutely upon the merits of this operation, but there seems to be already accumulated sufficient evidence of its success to entitle it to a trial in cases where tracheotomy is the only other resource.

#### EFFECTS OF DRUGS ON THE SWEATS OF PHTHISIS.

DR. ABLETSOFF, who has made a number of accurate observations on the effects of various drugs upon the sweats of phthisical patients, finds that hydrochlorate of pilocarpine, given in doses of  $\frac{1}{10}$  of a grain, produces no limitation of the sweats in a very large proportion of cases ; but its use frequently causes or increases gastro-intestinal irritation and sleeplessness, and, in fact, makes the general condition of the patient worse. With doses of from  $\frac{1}{8}$  to  $\frac{1}{4}$  of a grain the diurnal and nocturnal loss of weight almost always increases, and with doses of from  $\frac{1}{8}$  to  $\frac{1}{4}$  of a grain the loss is augmented in the majority of cases. The reasons why this drug has been recommended for phthisical patients are probably to be sought in its expectorant action ; but though as a matter of fact the amount of sputum daily expectorated is increased by the drug, it has no advantages whatever over other remedies whose effects in other directions are not so deleterious. Homatropine, picrotoxine, and duboisine distinctly decrease the cutaneous perspiration in healthy subjects, the latter drug having the greatest effect. For phthisical patients, however, who are weakened by exhausting sweats, more

suitable drugs will be found in agaricine and homatropine, as duboisine and picrotoxine frequently produce other and undesirable effects.—*Lancet*, July 3, 1886.

#### ON CHLOROFORM-WATER.

DE BEURMANN recommends in the *Zeitschrift für Therapie* of April 1, 1886, diluted chloroform-water as an antifermentative agent, which is also a local anæsthetic for mucous membranes. It is also useful as a mouth-wash in toothache, and given internally in cardialgia and dilatation of the stomach. In various decomposition processes in the stomach, in vomiting (especially of pregnancy), and as a vehicle for sedative and narcotic remedies, chloroform-water is, in Beurmann's estimation, unexcelled. The following are some of his favorite prescriptions in which the chloroform-water is exhibited :

℞ Aque chloroformii saturat., ℥vi;  
Aq. aurantii florum, ℥ii;  
Aq. dest., ℥iv. M.

S.—Teaspoonful for a single dose.

℞ Aq. chloroformii dilut., ℥iv;  
Aq. aurant. flor.,  
Syr. simpl., aa ℥i;  
Morph. hydrochlor., gr. ss;  
Pot. brom., gr. 15. M.

S.—Dessertspoonful several times daily.

℞ Aq. chlorof. dil., ℥iv;  
Aq. flor aur.,  
Syr. papaveris, aa ℥i;  
Pot. brom., gr. 15. M.

S.—Dessertspoonful as a single dose.

℞ Aq. chlorof. dil., ℥iv;  
Aq. menth. pip.,  
Syr. simpl., aa ℥i;  
Sodii salicyl., ʒi. M.

S.—Tablespoonful as a single dose.

#### THE PHYSIOLOGICAL ACTION OF THE HEAVY OIL OF WINE.

The heavy oil of wine as one of the component parts of Hoffmann's anodyne occupies a prominent but unrecognized place in our list of remedies.

According to the U. S. Dispensatory, this agent is formed by the distillation of alcohol with a large excess of sulphuric acid. The product of the distillation is generally in two layers, one of which contains the heavy oil of wine, while the other layer consists of sulphurous acid. For the purpose of separating any ether which may be in the oily layer, it is exposed to the air for twenty-four hours, when

it is washed with water, thereby removing any sulphurous acid which may contaminate it, and after these two processes have been accomplished the oil is ready for the market. Notwithstanding the fact that Hoffmann's anodyne is so frequently used, and has for so long a time occupied a prominent place in the household, and a useful one in the profession, curiously enough, nothing seems to have been done toward increasing our knowledge of its composition or of its physiological effects. Its formation is generally accounted for in the following manner :

When sulphuric acid and alcohol are added together, one of the results of their union is sulphovinic acid ( $C_2H_5HSO_4$ ); but if the sulphuric acid be in great excess the sulphovinic acid is partially decomposed, forming the heavy oil of wine. The mixture now consists of ethyl-sulphate, ( $C_2H_5$ ), $SO_4$ ; ethyl-sulphite, ( $C_2H_5$ ), $SO_3$ ; and ethylene,  $C_2H_4$ . Two forms of this ethylene are known, viz., etherin and etherol, and the mixture of these two separate forms of ethylene alone, forms the *light oil of wine*.

The same doubt seems connected with the specific gravity of the heavy oil. Sadtler believes 1.133 to be the most correct estimation of its specific gravity yet made.

DR. H. A. HARE (*Med. News*, July 10, 1886) has recently performed a number of experiments with this oil to discover what part was played by this drug when administered with alcohol and ether in Hoffmann's anodyne. He finds that in small doses the arterial pressure is increased, while large doses decrease arterial pressure. Small doses increase the rate of the pulse, very large doses are required to diminish the pulse-rate, small doses increase the force of the heart, while large doses do not decrease it unless extremely large quantities are given. These experiments were made with the oil alone, and show that even although in the officinal preparation its action may be masked by the more powerful and more diffusible stimulants, it at least does not occupy an inert position in the anodyne mixture.

Dr. Hare concludes from his experiments,—

*First*.—The belief in heavy oil of wine being the quieting agent in Hoffmann's anodyne, is fallacious.

*Second*.—That the calmative effects of this mixture depend largely on the ether rather than on the oil.

*Third*.—It would seem probable that in Hoffmann's anodyne we possess an agent in which there are linked together three drugs

of undoubted power, each one of which successively substitutes the other, stimulating the system in the order here named, viz., ether, alcohol, and the heavy oil of wine.

On animal temperature, as ascertained by the thermometer in the rectum, no effect is produced, even when the arterial pressure is very low. That large doses of the heavy oil of wine are in no way possessed of toxic effects, was proved by the fact that 30 c.c. of the drug given by the mouth to a small dog, weighing twelve pounds, failed to produce any apparent symptoms, except, perhaps, to stimulate him slightly. While the odor of the oil is penetrating, it is by no means disagreeable, and it possesses but little taste other than that of the presence of an oily substance.

---

#### ON THE HYPODERMIC USE OF IODIDE OF SODIUM.

DR. ARCARI, of Mailand, as we learn from the *Wien. Med. Woch.*, No. 4, 1886, is in the habit of applying iodide of sodium hypodermically in cases in which the internal use of the drug has to be suspended on account of resulting gastric irritation. He makes two injections daily, the dose ranging from 4 to 15 grains.

The results obtained by Arcari in syphilis with the hypodermic employment of iodide of sodium were quite as satisfactory as with any other mode of treatment. The quantitative examination of the urine revealed that in the cases showing favorable results of treatment the elimination of iodine proceeded slowly and scantily, while in the cases with negative results this elimination was quick and ample. This fact led Arcari to conclude that in the latter cases larger doses had to be given for a long time in order to obtain even here favorable results. To prevent an undue burdening and irritation of the alimentary channel, the alternate internal and hypodermic application suggests itself wherever large doses of the iodine salt are required.

---

#### RADICAL CURE OF VARICOCELE BY EXCISION.

*Il Bulletino* of the Royal Academy of Medicine of Genoa (No. I., 1886) reports a case in which Professor Ceci successfully treated a large left varicocele by excising the dilated spermatic venous plexus. The patient, aged 22, suffered great inconvenience in consequence of the enlargement. Under chloro-

form, an incision two and a half inches long was made on the left outer side of the scrotum down to the vein, the distention of which was maintained by an assistant exercising pressure at the external abdominal ring. With a director, the vas deferens and the spermatic artery were carefully isolated from the vein, which was secured with two catgut ligatures at the abdominal ring and near the testicle. The varicose venous plexus was then excised. The skin wound was closed with a catgut suture, a drainage-tube having been placed in the lower angle. On the eighth day, when the dressing was changed, there was some œdema of the scrotum; this part, as well as the inner surface of the thigh, was the seat of carbolic eczema, and carbolic necrosis had attacked the edges and the bottom of the wound. These symptoms disappeared under borax and iodoform, and the patient made a perfect recovery. Professor Ceci considers that the technical progress in operations for varicocele due to the influence of aseptic and antiseptic precautions, justifies preference for excision of the vein over difficult and complicated methods.—*Lancet*, June 26, 1886.

---

#### FURTHER OBSERVATIONS ON URETHAN.

We abstract DR. KRAEPELIN'S report on the action of urethan, as published in the *Neurologisches Centralblatt*, No. 5, 1886. The observations of the author comprise two hundred single doses and thirty-four different cases. The dose ranged between 15 and 45 grains, and in two cases only doses of 60 to 75 grains were given.

Kraepelin emphasizes at the very beginning of his paper that the drug produced in no instance any untoward secondary effects, only in the case of an alcoholic subject suffering from gastric catarrh, the stated large quantity of urethan caused vomiting. Interference with the appetite was never observed even where the drug was given for several weeks in succession. Ten to fifteen minutes after ingestion of the drug a quiet sleep ensues, lasting usually several hours, and from which the patients awake refreshed. If this sleep is interrupted by any external causes, the hypnotic, effects assert themselves again after the removal or disappearance of the interference. Urethan, however, is not an energetic hypnotic and fails usually in cases of intense or even considerable excitation, where it is far inferior to paraldehyde. In delirium tremens especially Kraepelin saw no effects as observed

by Sticker. Again, urethan is no anodyne, it does not remove pain, and in this respect can of course never replace morphine. In combination with morphine, urethan seems quite useful.

Kraepelin mentions as especial indications for urethan the affections of the melancholic and paralytic type; in mania and, as intimated above, in delirium tremens urethan is useless, and paraldehyde ought to be resorted to. Hence we see that only conditions of slight excitation or depression constitute the principal indications for urethan; besides, it is claimed to be useful in exhausting diseases even when fever coexists.

The drug has certain advantages over paraldehyde, which cannot be questioned: among these are the longer duration of its effects and the absence of gastric irritation after its use.

Urethan can be taken simply in a watery solution or, to correct its taste, with tinct. aur. cort.

#### *SOME CERTAINTIES IN THE THERAPEUTICS OF EPILEPSY.*

DR. C. L. DANA has written a paper with the above title, which is published in a recent number of the *New York Medical Journal*. His conclusions are summarized in the following statements:

1. Diet, exercise, and proper hygienic treatment rank above all other single therapeutic measures.

2. The bromides take the second rank in the treatment of epilepsy.

All bromides act alike in this disease. If one does not cure another will not. Occasionally changing and mixing reduces the attacks for a time, and benefits the stomach.

3. The best bromides are those of potassium, sodium, ammonium, and hydrogen (hydrobromic acid); possibly we may add nickel.

4. Bromides may be given in daily doses of  $\mathfrak{z}$ i, increased gradually until the attacks are suppressed, or the dose reaches  $\mathfrak{z}$ iv to  $\mathfrak{z}$ i daily. Few patients can tolerate more than this latter dose. Thorough bromidization should be always tried, if necessary to stop fits, and it may be occasionally repeated. But bromidization is sometimes injurious, even making the disease worse, and it must always be employed with caution.

5. When the fits are suppressed, the bromides should be carefully reduced, but never entirely stopped for at least two years after the last fit.

6. In most cases, and especially in noctur-

nal epilepsy, an extra large dose of bromide should be given at night.

7. It is very important that bromides should be chemically pure, that their use should be continued a very long time, and that their depressing effects should be offset by tonics and all possible roborant measures.

8. The best non-specific adjuvants (drugs) to the bromides are potassium iodide (in syphilitic epilepsy), potassium bicarbonate (in lithæmic and rheumatic states), carbonate of ammonium, the hypophosphites, arsenic, iron, and quinine.

9. The other chief adjuvants to the bromides are diet, exercise, a regular life, hydrotherapy, counter-irritation on the neck, and in the line of drugs, zinc, belladonna, strychnine, valerian, and the nitrites. Combinations of bromides with the other drugs mentioned will lessen attacks when bromides alone will not.

10. The best substitutes for the bromides, when these do no good or do harm, are belladonna, zinc, strychnine, glonoin, borax, and alteratives.

For nocturnal epilepsy, increase the dose of bromide at night, and add chloral or digitalis. Give also, if needed, strychnine. Raising the head of the bed or making the patient sleep in a chair at night are measures to be tried.

For the status epilepticus give large enemata of chloral, and use emetics and purges. Venesection is often efficacious, morphine is dangerous, chloroform is only palliative, and nitrite of amyl is of little value.

#### *THE INELIGIBILITY OF ANTIPYRIN IN PNEUMONIA.*

Observations of untoward effects produced by newly-introduced drugs, or of their failures in certain affections in which they have been recommended, ought to claim the interest of the practitioner as highly as reports on their medicinal virtues and efficacy. It is a positively objectionable feature of many contributors to the therapeutic press that they explicitly discuss the advantages of drugs, and dwell on the constant expansion of their sphere of usefulness, while paying too little attention to their objectionable aspects and the instances of their clinical failure. The THERAPEUTIC GAZETTE has repeatedly opened its columns to this unjustly neglected field of therapeutic knowledge. In the case of antipyrin, which is gradually becoming a popular antipyretic, it is of course very desirable to

know what the drug cannot do and to which untoward symptoms it can eventually give rise.

DR. POSADSKI (vide *Ieshenedjelnaja Klinitscheskaja Gazeta*, No. 30, 1885) reports that he has treated twenty-five cases of croupous pneumonia with antipyrin, giving daily doses of 15 grains to 2 drachms, and single doses of 7 to 30 grains. Simultaneously, he treated twenty-three cases of croupous pneumonia with calomel, in order to be enabled to compare the results of both forms of treatment. Calomel was given in doses of  $\frac{1}{4}$  grain four times daily. All patients were vigorous men, ranging between 26 and 30 years of age, and were admitted for treatment at the third or fourth day after the beginning of the affection. The average duration of the pneumonia in the patients treated with antipyrin was 8.1 days; in those treated with calomel, 7.1 days. In the latter set of patients, the termination of the affection presented invariably what Posadski calls a critical decline; in the former, a gradual resolution. In other words, the febrile symptoms disappeared completely, and sooner under the calomel treatment, and gradually and later under the antipyrin treatment. In five instances collapse was observed to follow after the use of antipyrin, a condition to which calomel of course could never give rise. The effects produced by the two drugs on the pulse and respiration were not materially different. In four cases antipyrin caused vomiting, and in two others a peculiar measles-like eruption of a very itching nature, affecting both skin and mucous membranes. In eleven cases the urine presented a singular dark cherry coloration, and contained a large quantity of antipyrin. The bodily weight showed a greater daily fall under calomel than under antipyrin, though its rise proceeded more quickly under the former drug.

The action of antipyrin on the temperature curves is, according to our observer, neither a constant nor a prompt one, and alongside of the above-mentioned other disadvantages does not justify the exhibition of the drug in pneumonia.

#### RADICAL OPERATION FOR HERNIA.

An improved operation for the radical cure of hernia has for some time past been practised by Drs. SVENSSON and ERDMANN, surgeons to the Sabbatsberg Hospital at Stockholm. A ligature is applied to the neck of the hernia, and the sac is cut off below the

ligature, the contents being previously examined by means of an incision into the sac and returned; or, if only omental, excised together with the sac. In congenital hernias the upper part of the sac only is removed, and where the large bowel is included in the hernia and adherent to the sac wall, this, after being separated from the surrounding tissue, is returned, together with the large intestine, and the rents of Poupart's ligament united by sutures. The dressing employed is iodoform and boracic acid, the wounds being washed with sublimate solution. Since this has been substituted for carbolic gauze, abscesses, which used to occur frequently, have become rare. Of the forty-eight cases thus operated on, none of which were selected, thirty-eight were permanently cured, at least no return of the hernia occurred within six months: in twenty per cent. it returned, but in a less severe form.—*Lancet*, June 26, 1886.

#### THE ACTION OF THALLIN ON THE ANIMAL ORGANISM.

DR. TSCHISTOWITSCH publishes in the *Ieshenedjelnaja Klinitscheskaja Gazeta*, No. 30, 1885, the results of a series of experiments made with thallin on frogs, rabbits, and dogs, as follows:

1. The sulphate of thallin, employed in doses of 0.02 to 0.1 pro kilo. of the bodily weight (per os, per rectum, subcutaneously or intravenously), has in healthy animals a very uncertain action on the temperature. There is no direct proportion ascertainable between the quantity of the drug employed and the fall of temperature.
2. In febrile animals, however, the temperature falls proportionally to the quantity of the drug employed. The temperature rises again after the lapse of two to six hours. The drug causes no vomiting.
3. The blood-pressure in febrile dogs is not materially altered by doses of thallin.
4. Intravenous applications of 0.02 of thallin cause a fall of the blood-pressure and a reduction of the number of ventricular contractions.
5. The fall of the blood-pressure refers principally to the action of the drug on the peripheral vaso-motor apparatus, and partially only to its impression on the heart itself.

As to the antibacterial action of thallin, our observer found that the alcoholic fermentation of grape-sugar was checked by the presence

of 0.1 per cent. of thallin, and wholly prevented by five per cent. of the drug.

**TETANUS CURED BY REMOVAL OF COMPRESSION FROM THE RADIAL NERVE.**

According to the Paris correspondent of the *British Medical Journal*, July 3, 1886, a remarkable case of traumatic tetanus was recently cured by the removal of compression from the radial nerve. A boy, aged 14, was admitted to Conrad Brunner's wards at Zurich; for a fracture of the left radius, which had occurred three weeks previously. The fourteenth day after the fracture, the child observed that he could not stretch the fingers of the left hand; his parents noticed that, when he walked, his body was bent forward. The symptoms became more and more marked; the child had bad nights, and was sent to the hospital. Symptoms of tetanus, risus, trismus, and emprostotonos, were marked. On examining the patient, there was evidence of a fractured epiphysis of the radius badly reduced, and a bulky callus just below the articulation. It seemed evident that the tetanus resulted from compression of the radial nerve by the callus. The parts were exposed by incision, when it was found that there was pressure of the nerve by new formations attached to the callus. The compressed nerve was set free, and the prominent portion of the radius resected. The symptoms of tetanus slowly disappeared; the patient had morphine injections. Three weeks after the operation the boy was cured.

In the same issue reference is also made to the fact that Dr. M. L. MOREAU publishes, in the *Alger Médical*, January and February, 1886, notes on a case of tetaniform symptoms cured by rest, sedatives, and electricity. The patient had trismus and opisthotonos, without any apparent reason; his intelligence was intact. He recovered in four days, during which period morphine and chloral were given in full doses, and the patient was kept thoroughly at rest, and was enveloped in cotton-wool. The patient had presented similar symptoms fourteen years previously, in consequence of injury to the scalp from a nail. On the present occasion another equally insignificant reason was suggested. The patient was a neuropath, and in order to obtain relief from his condition, he covered his body with needle-punctures by using an instrument similar to a cupping apparatus. These recurring tetanic attacks indicated a constitutional predisposition which M. Moreau sought to ex-

plain by hysteria, but the symptoms were not sufficiently marked to justify this diagnosis, nor was there any evidence of poisoning by strychnine. A carefully-kept register of the patient's temperature during the attacks would perhaps have furnished some data, but this was not done. The most probable hypothesis was that repeated cutaneous irritation, practised on a neurotic patient, provoked accidents of a tetaniform character.

**INFLUENCE OF SALICYLATE OF SODIUM ON THE ELIMINATION OF NITROGEN AND URIC ACID.**

DR. SALOMÉ, of St. Petersburg, communicated to the *Wien. Med. Jahrb.*, iv. p. 463, 1885, his observations on the influence exerted by salicylate of sodium on the elimination of nitrogen and uric acid. We condense his principal conclusions as appearing in *Schmidt's Jahrbücher*, April, 1886, p. 133. Wolfsohn, of Königsberg, and Virchow, ascertained first a reduction then an increase of the nitrogenous elimination after administration of the drug to dogs. Byasson noticed likewise the same increase on his own person and in rheumatic individuals. But as Horbascewski found a decrease of the nitrogenous elimination on his own person after taking salicylate of sodium, Paschki concluded to re-examine the entire question by observations on his person. Taking the drug in doses of 3 grains to 13 dr., and recovering the nitrogenous elements in urine and fæces, after the Ludwig method, he arrived at the following conclusions: The nitrogenous elimination is not augmented by doses of 3 to 75 grains. After doses of 2 dr., an increase occurs on the following morning, after doses of 13 dr. on the same day reaching its maximum, also on the next morning. After a dose of 2 dr., a decrease in the elimination occurs on the second day, and reaches its minimum on the sixth day. After smaller doses (3 to 20 grains), the elimination is somewhat reduced.

**ON NERVOUS PALPITATION OF THE HEART AND ITS TREATMENT.**

The editors of the THERAPEUTIC GAZETTE do not hesitate to exceptionally devote the columns intended for brief and condensed abstracts of foreign therapeutic matters to full translations, if they meet with an article combining scientific interest with practical worth to so eminent a degree as in the case

of Dr. SKORCZEWSKI's paper, appearing under the above heading in the April issue of the Vienna *Zeitschrift für Therapie*. The paper, with omission of some unimportant statistical matters, reads as follows :

"Nervous palpitation of the heart is an affection which develops without any visible and, moreover, without any anatomical causes, and is based upon the very disagreeable sensation of an exceptionally prominent and augmented cardiac action. The elder writers comprised under this category all morbid processes characterized by an increased heart's action, while at present we exclude all affections not referring to a purely nervous cause but to anatomical alterations, and certain special lesions known as angina pectoris and Basedow's disease. After this exclusion we have left the genuine nervous palpitation known also as cardiopalmus cardiagnus.

"The augmented cardiac action is caused by a functional interference with its nerves, which in its turn may result either from an irritation of the cardiac accelerator (the sympathetic) nerve, or from a paralysis of the cardiac inhibitory nerve (pneumogastric), or any point of its course from the centres in the spinal cord to the centres in the heart. But it is very difficult, and sometimes impossible, to determine the cause of the palpitation and the anatomical site of the cause.

"In spite of the frequency of nervous palpitation, few authors have gathered pertinent statistical materials. In my practice I found the palpitation in 6.4 per cent.\* of all patients, but much more frequently in women than in men (proportion 8 to 1).

"The palpitation appears with a varying frequency in various ages. In females I have often noticed it already between the fifth and the tenth year (1.6 per cent.), and between the tenth and fifteenth year (2.1 per cent.). Most frequently, however, the affection appears between the fifteenth and twentieth year (20 per cent.), then between the twenty-first and thirtieth year (18.3 per cent.). Between the thirtieth and fortieth year the percentage falls to 9.7, between forty-one to fifty to 3.7, and beyond the fiftieth year we find but very few cases (1 per cent.).

"In men the affection does not appear before the age of twenty, and remains stationary regarding frequency up to the forty-fifth year; later it becomes very rare (0.5 per cent.).

"Chlorosis and all the blood dyscrasias play

a very important rôle in the development of nervous palpitation in a similar manner, as has been supposed in the case of Basedow's disease (Friederich, Gräfe, Romberg, Taylor). In the cases coming under my observation 76 per cent. showed a simultaneous dyscrasia of the blood, 26 per cent. chlorosis, 35 per cent. anæmia, 36 per cent. malarial intoxication. Texta believes that in malaria the palpitation refers directly to the engorgement of the spleen, though my own observations have not confirmed this view.

"Various authors, such as Traube, Henoch, Murchison, and Frerichs, have called attention to the frequent connection of nervous palpitation with digestive troubles, a view which my own observations have confirmed.

"Botkin found the cause in one case of nervous palpitation in the so-called wandering kidney. In 101 cases of wandering kidney treated by me I observed nervous palpitation in 10.8 per cent.

"In affections of the genital tract I noted nervous palpitation in 12.1 per cent., and especially in structural alterations, such as new formations, flexions, versions, and the products of inflammation. In dysmenorrhœa and menorrhagia nervous palpitation is a common complication.

"In nervous troubles the palpitation appears especially frequently (86 per cent.). The following specification throws an interesting light upon this connection: General neuroses,—neurasthenia, spinal irritation, hysteria, hypochondria, 77.8 per cent.; megrim, 27.0 per cent.; intercostal neuralgia, 10.2 per cent.; neuralgia of the pneumogastric nerve and myalgia, 4.3 per cent.

"The clinical appearances of nervous palpitation are very varying. The patients describe the sensation in different manners. Some are unable to describe it at all, others complain of a trembling of the heart or of powerful movements after which the muscle appears to cease working. Sensations of pain and pressure are almost universally admitted. Being asked to localize their sensations, the patients again give wholly different answers. Some point to the region of the left side of the heart, others to the middle of the chest or to its entire left side, others again to different extremities. Some describe their sensation as proceeding from the heart and wandering over the whole left side of the chest, and occasionally the palpitation is said to be felt most on the neck or along the spinal column. The palpitation paroxysms differ also in the same person in duration and frequency. Preisendörfer ob-

\* All stated percentages refer to 2883 patients, among whom were 185 with nervous heart palpitation.

served paroxysms lasting several hours, and Gerhardt some lasting several days.

"In the cases coming under my observation I noted three different groups,—1. Those with an augmented apex-beat; 2. Those with an increased frequency of the beat; 3. Those without any alteration of the heart's action.

"The clinical course of the palpitation is usually parallel with that of the affections which have caused it, the palpitation remaining, in exceptional cases, only after the disappearance of its causative agencies. In such cases our affection calls of course for a special treatment. A long duration of the palpitation may give rise to serious troubles, and predisposes to anatomical alterations.

"The therapeutics of nervous palpitation, when resulting from other primary troubles, must first be directed to the removal of these. It is especially important to do away with any existing abuse of liquids, such as coffee, tea, and alcoholic drinks, and to observe strict dietetic and hygienic precautions. Indulgence in smoking is particularly objectionable. The affections of blood-dyscrasia (chlorosis, anæmia, malaria), of the nervous, digestive, and genital apparatus, call, of course, for an especial treatment. For the removal or lessening of the intensity of the paroxysms various methods of treatment have been recommended.

"Preisendörfer advocates pressure upon the pneumogastric nerve, while Mühlberger recommends massage of the epigastric region together with derivative drugs.

"Schröter employed successfully cold or ice applications to the heart, and Rosenbach ether locally for the same purpose. Digitalis, which is recommended by Schröter, is wholly disapproved of by Leyden in this affection, also in Basedow's disease.

"Leyden claims that narcotics, especially morphine, given internally, or better hypodermically, give gratifying results in the paroxysms of angina pectoris, based upon sclerosis of the coronary arteries, and Rosenbach and Schröter obtained good results with these remedies also in nervous palpitation. Chloral, chloroform, and ether also have the reputation of favorably influencing the paroxysms. The first remedy is to be given internally, the two others both as inhalations and internally in large doses ( $\frac{1}{2}$  to 1 teaspoonful).

"Rosenbach recommends also bromide of potassium in large doses (30 to 45 grains) and iodoform (3 to 7 grains). Nitrite of amyl, first introduced seventeen years ago by Lauder Brunton, enjoys still an excellent reputa-

tion. Hay recommends this remedy, and also nitrite of ethyl, nitrite of methyl, and particularly nitrite of sodium.

"Hamond, Hay, and Green speak also well of very minute doses of nitro-glycerin (1 to 3 to 10 drops of a one per cent. solution).\*

"Omitting all other drugs, which, though recommended from various physicians, have never attained any popular hold in the treatment of palpitation, I proceed to allude to the results which the above remedies have given in my hands.

"Pressure upon the pneumogastric nerve, massage, and cold applications appeared in no way to favorably influence the affection. Morphine, though a great stand-by in all painful troubles, is not well borne by patients of the nervous and hysterical type, and therefore its exhibition in palpitation is little recommendable. Nitrite of amyl and nitro-glycerin give but doubtful results when first exhibited, and scarcely any later. The following measures constitute my routine treatment. During the paroxysm of the palpitation I order cold applications to the region of the heart, provided they are—what is not always the case—well borne by the patient. Besides, I prescribe antispasmodic remedies, among which I prefer a solution of bromide of sodium, 15 to 30 grains, to be given either at once or in two doses. I also give the patient aqua laurocerasi, with equal parts of tincture of valerian (or of tinct. cann. indic., or tinct. castorei sibirici), to be taken in doses of 5 to 10 drops every few minutes. In frequently returning paroxysms I order a powder, consisting of bromide of sodium (7 grains) and quinine ( $1\frac{1}{2}$  to 3 grains), to be taken three times daily before each meal, and Fowler's solution (5 to 10 drops in a spoonful of sweetened water after the meals). This medication is to be kept up for several weeks.

"Electricity gives undoubtedly good results in this affection. Few therapeutists, however (like Duchenne), advocate faradization; the majority (among these Eulenburg, Huchard, Meyer, Remak, and Ziemssen) prefer galvanization. Ziemssen has directly proven by experiments that the constant current influences the heart like the striped muscles, and that the effects of the current, if applied to the thorax walls, are just the same as if applied to the heart directly. Ziemssen obtained wholly negative results from faradization.

\* We miss the mentioning of the iodide of sodium or potassium, which have recently been successfully tried by French physicians.

The application of the current can be effected in various manners. Ziemssen recommends to place one electrode to the sternum and the other to the back, at a height corresponding to the position of the heart. Eulenburg places the anode over the heart, and the kathode like Ziemssen, or the anode to the sternum and the kathode to the neck. Erb advocates the same method.

"In the patients treated by myself I have invariably placed the anode on the neck in the region of the nerve-trunks, and the kathode on the apex. After a couple of minutes I could always notice a considerable decrease in the frequency of the apex-beat (10 to 30).

"After the application the patients usually pronounced their condition improved. Eminently successful results could be obtained in the paroxysms returning several times daily, a few faradic applications usually sufficing to either remove the paroxysms wholly or to lessen their severity. Satisfactory results were likewise obtained in intercostal neuralgia and cardialgia.

"It is possible that the great success of galvanization obtained in my patients is partly to be attributed to the simultaneous use of medicinal waters (chiefly of iron), which I invariably prescribe in this affection. It is an indisputable fact that iron exercises a tranquillizing influence upon the action of the heart not only in nervous palpitations but also in developed cardiac defects, and even in incomplete compensation."

#### HOANG-NAN, A REMEDY FOR HYDROPHOBIA.

DR. BARTHÉLEMY has for years tried the effects of hoang-nan in paralysis, dyspepsia, chlorosis, and several skin-diseases, and appears to have attained such favorable results as to lead him to further trials of the drug. As we learn from the *Bull. Génér. de Thér.* (February 28, 1886), Barthélemy gave the drug to a patient who, having been bitten by a mad dog three weeks previously, presented the characteristic symptoms of hydrophobia. The drug subdued the reflex convulsions to a certain extent, but was unable to prevent the lethal exit.

In Tonkin the drug is often used successfully in large doses, and in short intervals, in cases of hydrophobia or snake-bite. It is interesting to learn that Barthélemy instituted with this drug a preventive treatment of hydrophobia in twenty-four cases. Two patients

showed the onset of the disease by various symptoms, such as complete insomnia, restlessness, hallucinations, barking, etc. In no patient, however, did the disease actually appear. The duration of the preventive treatment was on the average twelve days. The usual daily dose of hoang-nan is 15 grains, which suffices to produce the characteristic physiological effects of the drug, viz., increase of reflex motion, convulsions, and trismus. Lesserteur has given the drug to over one hundred persons bitten by mad dogs, and has always succeeded in warding off the hydrophobic attack.

Barthélemy concludes as follows: Either hydrophobia is transferred to man much more rarely than is usually supposed, or hoang-nan given to the bitten person during the period of incubation modifies so effectually the nervous system and the tissue-changes as to prevent the development of the hydrophobic virus.

#### ON THE ANTISEPTIC EFFECTS OF VINEGAR AND ITS UTILIZATION IN THE TREATMENT OF DIPHTHERIA.

Under this heading DR. FRIEDERICH ENGELMANN, of Kreuznach, publishes in the *Centralblatt für Klinische Medizin*, April 3, 1886, a paper which appears worthy of our attention. We present to our readers the following condensed abstract of it.

The fact of the absolute failure of the ordinary therapeutic measures in diphtheria induced Engelmann to institute trials with citric acid, which, as he had learned, was being successfully exhibited in the United States in this affection. The results obtained were sufficiently satisfactory and rather encouraging. In a grave case of diphtheria in the country, where citric acid could not be readily obtained, and a prompt interference was indicated, the author resorted to vinegar, and was gratified with the result obtained. He used partly ordinary vinegar, partly the official acetum, internally in the proportions of 1 to 4 as a gargle, 1 to 2 and even undiluted as a spray, 1 to 2 or 3 for painting undiluted.

Engelmann tested the antiseptic action of vinegar after the ordinary methods and was surprised at the degree of antiseptis obtained, which even surpassed that of a 5 per cent. solution of carbolic acid. He added to fluids crowded with bacteria a quantity of vinegar and 2½ and 5 per cent. solutions of carbolic acid separately, and obtained the following astonishing results after having transferred the fluids to gelatin-plates:

	First Day.	Second Day.	Third Day.	Fourth Day.	Fifth Day.
Vinegar, 2 to 10.....	.....	Numerous colonies.	Likewise.	Likewise. Soil partly fluidified.	Soil fluid.
Vinegar, 3 to 10.....	.....	.....	.....	.....	No colonies.
Vinegar, 4 to 10.....	.....	.....	.....	.....	"
Vinegar, 5 to 10.....	.....	.....	.....	.....	"
Carbolic acid, 2½ per cent., 2 to 10.....	Innumerable colonies.	Soil fluid.	.....	.....	.....
Carbolic acid, 2½ per cent., 3 to 10.....	Innumerable colonies.	Soil partly fluid.	Soil fluid.	.....	.....
Carbolic acid, 2½ per cent., 4 to 10.....	Innumerable colonies.	Soil partly fluid.	Soil fluid.	.....	.....
Carbolic acid, 2½ per cent., 5 to 10.....	Innumerable colonies.	Innumerable colonies.	.....	Soil partly fluid.	Soil fluid.
Carbolic acid, 2½ per cent., 10 to 10.....	.....	.....	.....	.....	.....
Carbolic acid, 5 per cent., 2 to 10.....	Very numerous colonies.	Soil partly fluid.	Soil fluid.	.....	.....
Carbolic acid, 5 per cent., 3 to 10.....	Numerous colonies.	Soil partly fluid.	Soil fluid.	Soil fluid.	.....
Carbolic acid, 5 per cent., 4 to 10.....	.....	Isolated colonies.	Numerous colonies.	Soil fluid.	Soil partly fluid.
Carbolic acid, 5 per cent., 5 to 10.....	.....	.....	.....	.....	No colonies.
Control .....	Innumerable colonies, soil partly fluid.	Soil fluid.	.....	.....	.....

This chart indicates that an addition of 3 to 10 of vinegar suffices to completely check the development of micro-organisms, while of a 2½ per cent. solution of carbolic acid an addition of 10 to 20, and of a 5 per cent. solution of carbolic acid an addition of 5 to 10 was required for the same result.

Other comparative researches of the same nature gave invariably identical results.

If these experiments are accurate, and if their results should be confirmed by other observers, we possess in vinegar an antiseptic agent of the highest type, which strangely has hitherto escaped the attention of therapeutists. Even Koch never alludes to vinegar as an antiseptic medicine in any of his experiments of disinfection. Alongside of its disinfecting efficacy, rivalling and surpassing apparently that of carbolic acid, vinegar possesses such other advantages as will insure for it the first rank whenever an antiseptic remedy is needed for internal use and for the mucous membranes of the mouth and pharynx. It is not caustic nor irritating, and is wholly innocuous. Later researches will no doubt determine whether and to what extent the well-known action of acetic acid on the animal cells and tissues need be considered in the application of this remedy.

The harmlessness of vinegar together with its alleged powerful antiseptic influence ought to induce practitioners to give the remedy a trial in diphtheria. If it is not productive of good it can at least do no harm, and that is more than can be said of many therapeutic interferences practised in diphtheria.

## Reviews.

A SYSTEM OF PRACTICAL MEDICINE BY AMERICAN AUTHORS. Edited by Wm. Pepper, M.D., LL.D., etc., assisted by Louis Starr, M.D., etc. Vol. V. Diseases of the Nervous System.

Philadelphia: Lea Brothers & Co., 1886.

The editor of this work may well call attention with some pride to his success not only in the general character of the work, but in the punctuality with which its volumes have reached the subscribers. The number of articles, as given in the editor's "Valedictory," is 185, by 99 authors, covering, with indexes, 5600 pages.

The volume on the nervous system opens with a chapter on "General Semeiology of Diseases of the Nervous System; Data of Diagnoses," by E. C. Seguin, M.D., and is followed by one on "Localization of Lesions in the Nervous System" by the same author. This article is extensively illustrated, which much increases its great intrinsic value. The author has chosen, he tells us, by reason of limited space, not the "more interesting and logical" way of a general demonstration of "the organic independence and functions of various parts of the nervous system," with the classified "results of autopsies bearing on localization," but the method which he terms "a summary statement of the association of the symptoms with definite lesions." Whether the former method would have given us a better article we cannot say, but the one we have is of great value, though much condensed. "Mental Diseases," by Chas. F. Folsom, M.D., cov-

ers one hundred pages, and treats the subject of insanity with great thoroughness. Dr. Chas. K. Mills contributes "Hysteria," "Hystero-Epilepsy," "Catalepsy," and "Ecstasy," which are, as might be expected, not only valuable additions, but written in an exceedingly interesting style. The illustrations are also excellent. These articles cover over one hundred and fifty pages.

"Neurasthenia" is by H. C. Wood, M.D. This, while a short, is an exceedingly useful article, in which the author, while acknowledging the exceedingly vague outline of the disease, its relation with so many other definite conditions, its abuse as a cover for weak diagnoses, yet manages from these very circumstances to convey to the reader a vast amount of valuable diagnostic knowledge, and to present, through all its mists and envelopes, a "neurasthenia" clear cut, readily defined, and perfectly recognizable. Dr. Henry M. Lyman contributes "Sleep and its Disorders," which is a studious and interesting presentation of the perplexing problems involved in "sleep" and "dreams," "night-terrors," somnambulism, and hypnotism. He also studies the question of insomnia, lethargy, and apparent death, and has produced a standard article, which will be fully appreciated by the thoughtful student. "Acute Affections produced by Exposure to Heat" is also from the pen of Dr. H. C. Wood, who has identified himself with the subject, and carried its study to the extreme possible limits of the day.

Dr. Wharton Sinkler contributes chapters on "Headache," "Tremor," "Paralysis Agitans," "Chorea," and "Athetosis." Dr. S. Weir Mitchell one on "Vertigo." Dr. Mitchell believes that vertigo by no means depends upon a condition of cerebral congestion in anæmia, but that it is due in all cases to a disturbance of the cerebral nerve-ganglia, and that the attendant basal condition is but one incident in the attack. Dr. Sinkler's article on "Chorea" is rendered additionally valuable from his use of the statistics gathered in the case-books of the Infirmary for Nervous Diseases. Dr. Allen McLane Hamilton gives us two articles on "Local Convulsive Disorders" and "Epilepsy." Dr. Morris J. Lewis writes on "The Neural Disorders of Writers and Artisans." Dr. P. S. Conner on "Tetanus." Dr. Edward P. Davis on "Disorders of Speech."

Dr. Jas. C. Wilson writes three articles on "Alcoholism," "The Opium Habit and Kindred Affections," and "Chronic Lead-Poison-

ing." While all three are excellent, the chapter on alcoholism is of especial note. It is distinguished for its extreme care in statement and its breadth of thought. The intemperate advocate of abstinence and the weak-willed victim of excess will alike fail to extract comfort from the author's calm and judicial statement of the question. The following sentence may be taken as embodying the author's view of the moral aspect of the temperance question, p. 576: "The occasional moderate use of alcohol in the form of wine with food, and as a source of social pleasure, is not fraught with the moral or physical evils attributed to it by many earnest and sincere persons. It is, on the contrary, probable that the well-regulated and temperate use of sound wines, under proper circumstances and with food, is in the majority of individuals attended with benefit. Those who suffer from the effects of excesses do not usually reach them by this route, nor would they be saved by any amount of abstinence on the part of temperate and reasonable members of society;" and on p. 577: "The part which heredity plays in many of the most inveterate and hopeless cases of alcoholism is wholly out of proportion to the obvious and easily recognized part played by momentary temptation." The author has studied the question carefully in all its bearings, and, while by no means neglecting the medical aspect of the matter, has gone broadly over the whole ground, studying the variations of injury produced by the different alcohols, the effects of employment as a predisposing agency, the influence of heredity, and the various tangle of questions which the apostle of total abstinence has made into a sort of Chinese puzzle with which to fool himself as well as his followers. The same writer's article on "The Opium Habit and Kindred Affections" furnishes a good sequel to the chapter on "Alcoholism," showing how the removal of alcohol alone will by no means solve the question so long as any agent is procurable which can act as a stimulant or intoxicant.

"Progressive Unilateral Facial Atrophy" is by Dr. Chas. K. Mills. "Diseases of the Membranes of the Brain and Spinal Cord," by Dr. Francis Minot, who also contributes "Tubercular Meningitis," "Chronic Hydrocephalus," and "Congestion, Inflammation, and Hemorrhage of the Membranes of the Spinal Cord." Dr. John Ashhurst writes on "Spina Bifida," and Dr. E. C. Spitzka gives us two exceedingly thorough, readable, and interesting articles on "Anæmia of the Brain and Spinal

Cord" and "Chronic Inflammatory and Degenerative Affections of the Spinal Cord." Dr. Wm. Hunt contributes "Concussion of the Brain and Spinal Cord." Dr. Robt. T. Edes, "Intercranial Hemorrhage and Occlusion of the Cerebral Vessels, Apoplexy, Softening of the Brain, Cerebral Paralysis."

Dr. H. D. Schmidt writes on "Atrophy and Hypertrophy of the Brain" and "Diseases of One Lateral Half of the Spinal Cord." Dr. H. C. Wood, on "Syphilitic Affections of the Nerve-Centres." Dr. Chas. K. Mills and Dr. Jas. Hendrie Lloyd contribute the articles on "Tumors of the Brain and its Envelopes" and "Tumors of the Spinal Cord and its Envelopes," covering nearly one hundred pages with the two articles. Dr. Mary P. Jacobi gives us "Infantile Spinal Paralysis," an excellent and exhaustive study of the subject. "Disease of the Peripheral Nerves," by Dr. Francis I. Miles; "Neuralgia," by I. J. Putnam, M.D.; and "Vaso-Motor and Trophic Neuroses," by Dr. M. Allen Starr, conclude the volume.

Any thorough discussion of the merits of the various articles being precluded, we are sure that the work has suffered no falling off in its concluding volume, and we look in vain for a series of the kind which can equal it in practical value, and especially as a representative American work. We have already a number of similar works, European in their origin, whose value to us is diminished from the very fact of their foreign origin. If anywhere there are writers and thinkers, practitioners and experimenters, peculiarly fitted to instruct and assist the American practitioner in his work, they are to be found among ourselves. The whole tone of the work is familiar and American and original; in fact, there is a remarkable amount of originality in most of the articles. They display the result rather than the material and mechanism which produced it, and so completely does the work as a whole mirror to us the most advanced views of the day, that in all the rapidly shifting opinions of this changeable age, the *System of Medicine by American Authors* bids fair to survive as a text-book and authority for many years to come.

E. W. W.

A TREATISE ON THE DISEASES OF THE NERVOUS SYSTEM. By Wm. A. Hammond, M.D., etc. With one hundred and twelve illustrations. Eighth edition, with corrections and additions.

New York: D. Appleton & Co., 1886.

The motto from Horace still decorates the title-page, and reminds the reader of the ob-

vious fact that the present edition does not go very much beyond the previous ones in any noticeable respect. It is about the same in size, shape, and general appearance. It is modestly clothed in the same green muslin covers, though its pages are somewhat increased in number. A chapter has been added upon "Certain Obscure Diseases of the Nervous System," and the author declares that the work "has continued to receive approval at home and abroad to an extent beyond that ever given to any other work, of like scope and objects, published in any part of the world." Can it be possible that no work of "like scope and objects" has ever been published?

The new chapters, section vii., treat of tetany, Thomsen's disease, and miryachit and kindred affections. Tetany, which has been termed "a variety of intermittent tetanus" and "idiopathic contraction of the extremities," is more prevalent, the author imagines, upon the Continent than in either Great Britain or America. Still, he imagines it possible that in a modified form it occurs among us more frequently than is supposed, being "diagnosed as hysteria or as 'cramps.'" He describes certain prodromata, and gives us an extended description of the fully-developed condition. In regard to its diagnosis, he believes that "many cases have been reported as idiopathic tetanus." It is "also frequently diagnosed as hysteria," from which it radically differs. The contractions are greater, it affects more than one limb, and we would add that, judging from the author's description of the disease, the mental condition is different. In regard to its treatment, the bromides, we are told, are useful, and, "when properly administered, the contractions cease in the course of a few hours." The natural limit of the disease is stated by the author to vary from two days to two weeks or more. The author's method of employing the bromides is to give 100 grains, say, of sodium bromide dissolved in a half-glass of water at once. This should be followed by 30-gr. doses every two or three hours, and this should be repeated three times a day for a week or longer after the contractions are relieved, provided there is any evidence of a tendency to a return of the disease. He says, "I have never seen a case of tetany resist this treatment." Neither have we. Electricity, massage, etc., aggravate this disease, as also strychnine. The author considers it as "essentially a congestion of the spinal cord."

Thomsen's disease is one of those unfortunate diseases, or Thomsen is one of those unfortunate men who have given their own name to a disease. There is no proof that he ever had it himself; he only described it. It is characterized by "tonic spasms in the muscles, to which in the act of exerting them volitional impulses are sent, and which remain for some time after the movement is executed." This definition is rather labored, and would be improved if stated in another way,—characterized by tonic spasms, which occur as a continuation of a muscular movement originated by volition. The author considers it difficult, in the present state of our knowledge, to locate the lesion which gives rise to this affection, whether it is brain, spine, or muscles. The author says in regard to treatment, that there "are no data by which we can be guided."

In "Miryachit and Kindred Affections" the author quotes largely from the late Dr. Geo. M. Beard in regard to the "Jumpers," whom he identifies with the sufferers from miryachit, and ends the chapter with the remark "that it is very obvious that there is in these kindred affections a field for observation that is as yet comparatively unexplored," though what will become of rising men and specialists when all fields have been explored and nothing new can be found, and all old literature and exploded superstitions have been revamped and disposed of, is one of the sad questions of the by no means remote future.

E. W. W.

A MANUAL OF PRACTICAL THERAPEUTICS CONSIDERED IN REFERENCE TO ARTICLES OF THE MATERIA MEDICA. By Edward John Waring, C.I.E., M.D., Fellow of Royal College of Physicians, London, etc. Edited by Dudley W. Buxton, M.D., B.S., London, etc. Fourth edition.

Philadelphia: P. Blakiston, Son & Co., 1886.

As the author aptly remarks, the thirty-two years since the first appearance of this work have seen many important changes, and therapeutics has "advanced with rapid strides." The progress has been the more rapid ever since the old beaten track was abandoned, and a road made into the practically new world which the science now occupies. To accommodate the work to these changes, much old matter has been swept away and much new matter necessarily introduced. By this process the work has been materially benefited, the omissions, equally with the admissions, being a positive benefit; the bulk of the book being actually diminished, while its contents—its valuable contents—are much

increased. In looking over the book we find excellent articles on "Amyl Nitrite," "Apiol," "Apomorphine," "Antipyrin," "Boracic Acid." The article on "Cannabis Indica" is very full, as also that on "Chloral."

Under the head of "Acidum Oleacum" the unprinted story of the oleates is told. The article on "Opium" covers twenty-two pages. There are excellent articles on "Physostigma" and "Pilocarpine," "Quinina" appears instead of quinia, and we find on examination almost all the new drugs, with a good amount of information appended, even to Warburg's tincture, except paraldehyde, which is conspicuously absent, as it is from the new British Pharmacopœia. For convenience of reference we have an index of diseases as well as an index of remedies, and the book will be far more useful in its present shape than it ever was in previous editions.

## Correspondence.

---

LONDON.

(From our Special Correspondent.)

If there be one subject of greater therapeutical interest than another at this season in England, it is the result of the climatic treatment of the past winter upon our patients who are just returning from abroad. You know how greatly dependent we are on foreign health resorts, and how extensively we employ them in the case of diseases of the chest. Your own resources in the matter of climate as a means of cure are practically unlimited in number and variety. Yet you do not hesitate to avail yourselves in many instances of the winter sanatoria of Europe. I propose therefore in this letter to refer to some important aspects of the climatic treatment of phthisis as it is carried on in the higher Alpine valleys.

The value of the treatment of diseases of the lungs by cold mountain air is becoming more thoroughly established every year. Little by little the prejudice which once almost universally existed in favor of warm climates, and against the exposure of consumptives to anything approaching the temperature of ice and snow, has been broken down in the face of positive results which cannot be explained away. When an honest criticism is directed to the question at issue, and the whole character of Alpine winter climates estimated absolutely and relatively, it is found that, after

all, temperature has but little to do with the beneficial results. The ocean at any latitude, the desert of Libya, the prairies of Mexico, all exert an equally beneficial influence on phthisis. No doubt *dryness* of the high Alpine air counts for much. It is impossible for any one belonging to this country not to be struck by the extraordinary dryness of the air of the upper Engadine, or to avoid connecting with this quality the absence of that "raw, searching" coldness of the English climate and its consequences, which make winter so wretched and so dangerous a time with us.

Much the same may be said respecting the *stillness* of the air in these chosen Alpine valleys. The few clouds that are to be seen in the deep blue sky may be slowly driven across the firmament, but as a rule no breath of morning air stirs the snow-laden pines, nor provokes a cough from the consumptive as he bravely paces along the forest road. The exhilarating effect of *altitude* is also considerable; and the same factor is unquestionably powerful in assisting and accelerating the closure of cavities by pulmonary hypertrophy and generally increased activity of the respiratory and circulatory functions. The amount of *sunshine* enjoyed in these high quarters cannot but be invaluable to the ill-nourished, bloodless tissues of the consumptive. Only people like the Londoners, who are now condemned to nearly six months' comparative darkness every year from fog and smoke, can thoroughly appreciate, in my opinion, the precious blessing of sunshine to bodily and mental health.

Still, when we are the most impressed by the importance of these several elements of the mountain climate, there comes back to our mind the supreme value of the ocean, of sea-voyages, of the ocean with its variable temperature, its frequent fogs and rain, its gales and head-winds, and its absolute want of elevation, and we ask ourselves, what is it, then, in common to the ocean, to the mountain, to the desert, and to the prairie that is so precious a therapeutic agent to the *poitrinaire*?

There can no longer be any question but that the most precious element of climate is *purity of the air*. The day is happily now past when we needed to prove this statement. If the surgeon be asked what he considers the most important condition of healing *next* to purity or cleanliness, he will answer unhesitatingly, freeness of discharge, drainage, absence of unnatural tension. It may be questioned

whether the physician sufficiently appreciates this second condition of success in the treatment of lung-diseases accompanied by discharge, such as phthisis and chronic bronchitis, although expectorants have been a favorite method of treatment from time immemorial. Unquestionably part of the fever of pulmonary consumption is due to retention in cavities, as all know who have had to do with phthisis in the lower part of the lungs, pulmonary abscess, and bronchiectasis. We long to drain these cavities, and some very promising results in this direction have lately been obtained here by Dr. C. T. Williams, Mr. Godlee, Dr. Cayley, and Dr. Biss. But there are obvious limits both to operative proceedings on the lungs and to the use of expectorants, and it is clear that if we desire to diminish the discharges in phthisis, *we must prevent their formation*. Purity of the respired air appears from these considerations to be in a second way invaluable in phthisis. It is not only "aseptic," but by diminishing suppuration it prevents accumulations and further suppuration and ulceration; it dries the cavities; it promotes healing.

I have not dwelt upon these points for the purpose of writing a lecture on the influences at work in the treatment of phthisis, but to direct the attention of your readers to a matter of great importance in connection with the most famous of Alpine winter stations. I mean Davos-am-Platz. It is now admitted by all authorities that the first element of a proper climate, pure air, is fast disappearing from the Davos valley. This is an alarming fact, and demands our serious consideration. Davos has been too popular. It has been overdone. Its physicians, its most intelligent residents, those who own building land in and about the village, all tell us the same. The universal cry with them is, Send us no more patients; let us have even fewer winter visitors than now. The reason of this cry is not far to seek. You see it in the streets of houses crowded end to end along the roads which less than twenty years ago ran through a single Swiss hamlet; for you know that this means the crowding together of human beings of whom a large proportion are suffering from tuberculosis. Equally serious, the visitor cannot fail to notice that a cloud of smoke hangs over Davos, and he may find at ten o'clock in the morning that he cannot see twenty yards along the main street for fog. The very evils from which we banish our London patients meet them in one of the highest valleys of the Alps! This state of things will

never do. In the interests of Davos, which has proved a blessing to so many poor phthical patients, it is to be hoped that the place will get a chance of recovering itself.

The remedy is obvious, and fortunately is easily found. We must send our patients elsewhere. Other well-known winter stations must be patronized, and still others discovered, care being taken that, however favorable their situation, the error shall never again be committed of overcrowding and overgrowth. For the present there is no difficulty. Three other most excellent sanatoria can still receive an increase of patients with safety. Of these three St. Moritz is the best known. At the Kulm Hotel, which may be said to still accommodate all the winter visitors at St. Moritz,—a good hundred,—the living and the life generally are such as to give the best results and the greatest possible comfort and pleasure to Americans. The Kulm might be almost described as a modern Bracebridge Hall at Old Christmas, the company thoroughly social, the day's occupations of a robust kind on the snow or the ice, the evening's amusements within the house refined and entertaining.

The Maloia, about eleven miles from St. Moritz, is a place represented by a single large hotel, which in its internal arrangements has, unlike the Kulm, everything that modern science can do to make it unlike an English country house of sixty years ago. It is warmed, ventilated, and lighted in the most complete and successful way that steam and electricity can accomplish. No doubt the Maloia, which so far has attracted but some forty residents in its winter season, has a great future before it.

Wieson is a winter station which can be confidently recommended. It stands on the same river which flows through Davos, but on a steep slope, far above the bed of the stream with its fogs, where the sun strikes powerfully and cheerfully, and from which the snow disappears early and very quickly when the thaw has once set in.

Whilst these sanatoria are ready to receive more visitors, one of the most famous of Alpine health resorts, Pontresina, promises very shortly to open some of its hotels in winter to invalids. The proprietor of the Hotel Enderlin, which is beautifully situated, and furnished with every regard to comfort and sanitary completeness, has intimated his willingness to take a limited number of mild cases of lung-disease next season. With such accommodation, and with the skill and atten-

tion afforded by Dr. Ludwig, its resident physician, Pontresina can be confidently recommended by American and English practitioners.

#### SMALLPOX IN CANADA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Kindly allow me to correct an error which has crept into your article on "Sanitary Science" in the June number.

You say, "The outbreak of variola in Canada having been allowed by ignorant and careless municipal authorities to assume such alarming proportions," etc.

The authorities alluded to (Montreal, I presume) were neither ignorant nor careless. On the contrary, they thoroughly grasped the situation as soon as they were notified of the advent of two cases from Chicago. Unfortunately, one of the cases found its way into a large hospital in which there were a number of orphan children unvaccinated. It is generally known throughout America by this time that a large proportion of our population of French origin, excited by antivaccinators, and misled by poorly-educated physicians, who gave a very weak support to vaccination, if they did not entirely oppose it, refused point-blank to obey health ordinances, and also to allow their children or themselves to be vaccinated. Thousands of our people—in fact, one section of the city *en masse*—utterly opposed health measures, and it thus became exceedingly difficult to handle what in July and August had already threatened to become a formidable epidemic. Then came the riots, when the houses of the vaccinating physicians and health officers were attacked, and even the offices of the Board of Health in the City Hall.

Removal to hospital and enforced isolation became almost impossible, for, although a strike may be put down by force of arms, and a riot may be nipped in the bud by bayonets, it is somewhat difficult to enforce health ordinances in the same fashion.

Nevertheless, when the worst came, the sanitary authorities were not afraid to use force, where it would best produce a good moral effect. The officials were armed and their number largely increased, the doors of all infected houses were sealed up, and patrols mounted in front and rear. The services of the good nuns were invoked, and the municipal authorities supplied them with thousands of dollars to take provisions and medical comforts to the houses thus isolated. Every case

not susceptible of perfect isolation at home was obliged to go to hospital, and, if the patient would not go peaceably, he was taken by force. It would take too long to explain in detail all the difficulties which surrounded the position from the start. Suffice to say, by the most severe and stringent means one of the most fatal epidemics of modern times was cut short in midwinter, the hitherto most dangerous season for this disease in our Canadian climate. Of the 3164 persons who died up to December 31, 1887 were French Canadians, 181 other Catholics, and only 96 English-speaking Protestants. This tells its own tale so far as vaccination is concerned.

God grant you may never have the same experience in Detroit.

In conclusion, I would like to ask how you would proceed to vaccinate a man or his family against his will? Would you chain him down and do it by force? There's the rub.

Let the members of the medical profession do their duty, and see to the vaccination of the children they bring into the world, and also by giving every assistance to boards of health in their endeavor to popularize vaccination and health measures. A badly-vaccinated population will always be exposed to smallpox epidemics; but with a smallpox hospital always ready, and a stringent law on the statute-book requiring every case, without exception, to be taken to it, *by force if necessary*, boards of health may feel tolerably confident of preventing an epidemic, *always provided they are backed by a good healthy public opinion*, and have not a population to deal with who are violently opposed to vaccination, isolation, and disinfection!

Yours truly,

HENRY R. GRAY,  
Chairman Board of Health.

MONTREAL, July 7, 1886.

#### POTASSIUM PERMANGANATE IN AMENORRHOEA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In your June issue is an article on the use of permang. pot. as an emmenagogue, and asking for results. My conclusions after using it in about fifty cases are as follows:

1. It acts with certainty in about seventy per cent. in selected cases.
2. It may be given at any time, but preferably one or two hours after eating, as it is not so apt to sicken the stomach. I don't think it

is any more efficient when given on an empty stomach.

3. I have used the sulphate in a number of cases with less certain effect; the result attained, however, may have been accidental.

4. In most cases it produces an exhilaration of spirits.

5. It has a decided tonic effect.

6. It will become an indispensable therapeutic agent.

7. Its disagreeable effect on the stomach is best relieved by a combination of

Cerri oxalat., gr. i;

Cocaine hyd. chlor., gr.  $\frac{1}{4}$ ;

Bismuth. subnit., gr. v;

Pulv. ipecac., gr.  $\frac{1}{8}$ . M.

Ft. cachets, one every two hours.

Respectfully,

BENJAMIN MARSHALL, M.D.,  
Col. Phys. and Surg., N. Y.

924 SUTER ST., SAN FRANCISCO, CAL.

#### POTASSIUM PERMANGANATE IN AMENORRHOEA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Having noticed in the THERAPEUTIC GAZETTE of June 15, 1886, an article upon the emmenagogue effect of potassium permanganate with the request appended that any one who had tried it, either successfully or unsuccessfully, would let you know the details of his experience, I record my experience with it. When I first began the practice of medicine I found myself frequently in need of an efficient emmenagogue, and in reality found none, but after years of search I chanced upon this remedy through the experience of some one, and I have been well pleased with its effects as such, but dislike its tendency to irritate the stomach.

CASE V. will illustrate very well its claims as used by me. C—, æt. 18 years, health in every respect good, family history free from any venereal diseases or the manifestation of any transmitted affection; married at fourteen years, conceived, and aborted at the third month of pregnancy; her menses appeared once after and then became suppressed, and so remained for the last two years and over, with occasional head-symptoms. I preceded the permanganate of potassium, as is my custom, by introducing the sound at least three times during the first week of treatment, and puncturing the os tincæ to the depth of from the eighth to a quarter of an inch, then following up with 2-

grain doses in capsules, three times daily, just before meals, for four weeks. I have never used the manganese salts, being satisfied with the above salt. I can cite Case VI., which may be of some interest, in this connection. L—, æt. 19, well made, plethoric, unmarried, breasts well filled out, never menstruated, complained considerably of head-symptoms; treated her as I did Case V., and with satisfactory results in about three weeks. I regard the method as practised by Prof. E. S. Lewis, of the Medical University of Louisiana, of puncturing the os tincæ in two or three different places excellent, causing thereby a hemorrhagic tendency thereto, then follow on with the potassium permanganate. I could cite other cases, but think this sufficient, as I have never met with a failure in treating amenorrhœa or the various forms of suppressio mensium.

Respectfully,

E. E. SMILEY, M.D.

ABNER P. O., KAUFMAN CO., TEXAS, July 2, 1886.

#### *TREATMENT OF RHUS-POISONING.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In your very interesting reply to the query concerning the treatment of rhus-poisoning (vol. x. No. 7, p. 491), you barely refer to bicarbonate of sodium as a remedy; and yet in my own experience, gained in a life-long battle against the infection, being exceedingly susceptible to the intoxication, I have found no remedy which compares with it. Up to 1869 I was an annual sufferer with the trouble. So susceptible was I to infection that I could not come on the leeward side of the plant in the spring-time, especially early in the morning, without suffering. My head would swell until the features were almost indistinguishable, and the suffering was intense, especially if, as was frequently the case, the penis and scrotum were also attacked. During the spring of 1869 my hands became poisoned from contact with a bridle-rein or halter that had been tied around a fence-rail on which grew the rhus. Opening the blisters with a needle, and drying off the exudation with a blotting-pad, I accidentally applied a bit of litmus, and found that the fluid was exceedingly acid. I thereupon sprinkled some bicarbonate of sodium upon the opened pustules, and let it remain a few minutes. I was called into my office shortly afterwards, and, becoming immersed in business, forgot all about what

usually was something that did not allow me to forget it for a moment. To make a long story short, the eruption, instead of spreading as usual, dried up readily; and, acting on this hint, I afterwards used a strong solution of the bicarbonate whenever I was threatened with the poisoning. It has never once disappointed me, and so confident am I of its neutralizing effect, that now I take no precautions to avoid the poisonous plant.

I have since that time used the salt (bicarbonate of sodium) in my practice in similar cases, and, while I find some persons upon whom it does not have the desired effect, in so marked a degree at least, yet its action is sufficiently uniform to entitle it to a prominent place among the "specifics" for rhus-poisoning.

It must be remembered, however, in taking into consideration the claims of any remedy to specific action in this trouble, that aside from individual idiosyncrasies (which play a very prominent part), there are quite a number of varieties of rhus indigenous to the various parts of America, all of them more or less poisonous to certain persons, and all going under the vulgar names of "poison-oak" or "poison-ivy;" and, further, that it is quite within the range of probability that the poisonous principle may be contained in one variety in one chemical shape and in a different one in others.

FRANK L. JAMES, Ph.D., M.D.

ST. LOUIS, July 22, 1886.

#### *TREATMENT OF IVY-POISONING.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—As L. B. Parsell, M.D., would be "glad to hear from any of your subscribers in regard to the treatment of the poison of the wild ivy," and having been in the practice of medicine nearly half a century, and having practised for the first half of the time in the country, where I saw in the summer season usually several cases where even the whole surface of the body was swollen and vesicated, I may claim to have had some experience with this affection. In some cases the face was so swollen that the patient was unable to see,—not by coming into actual contact with the ivy, but simply by coming within a few feet of it when the vapor of the dew containing the poison fell upon the person; and having early found a most excellent remedy for this poison, I wish to make it known not only to Dr. Parsell but all whom it may concern.

Finding early in my practice that in the treatment of almost all cutaneous affections, where the skin was inflamed, stimulating applications *soothed* sooner than those supposed to possess the soothing power to the greatest degree, I ventured to apply in all cases of ivy-poisoning the following :

R Olive oil, ℥viii;  
Sulph. zinci, ℥ss.

This to be well shaken, and applied when the skin is involved, and the surface covered with old linen cloths. The itching and swelling will soon subside, the whole surface affected seemingly drying up, that is, if the application is made early. If later, and the surface is raw, the zinc will not cause smarting in the least, but heal it up. It is not generally necessary to apply the application more than *twice* before the cure is effected. It is well to wash the dried surface with lime-water to cleanse it about the fourth day, when the case will not require further treatment generally. It is a singular fact that only a few people comparatively are poisoned by the ivy. Some can walk through it, handle it, and even chew it, and suffer no harm from it. In my young days I never feared to walk through a bed of it, or to handle it. I have known whole families to be exempt from the effects of this poison.

J. M. BUZZELL, M.D.

PORTLAND, ME., July 23, 1886.

#### THE TREATMENT OF IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE :

GENTLEMEN :—I read with much interest your remarks about the treatment of ivy-poisoning. I have tried nearly all the different remedies you mentioned, with more or less success, and the words, "There is no specific for the cure of dermatitis venenata," are perfectly correct. I have seen many cases of dermatitis venenata, and in my opinion the different remedies acted differently, not on account of the healthy or unhealthy constitution of the individual, but on account of the difference in the plants by which the poisoning was caused.

The two cases under Dr. Morrow's observation, members of the same family, both in the initial features of the eruption, and both submitted to the same treatment, but with different success, are a perfect illustration of my opinion.

I herewith submit a formula which I have used lately, and with more benefit than any

other before. If Dr. Parsell, or any other of my confrères, should give it a trial with the same success I had, I would be glad to hear of it.

R Acid. carbolic., ʒi;  
Liquor. ammon. caust., ʒss;  
Ol. olivæ, ʒiii. M.

S.—Compresses to be moistened, and applied every two hours to the affected parts. If the eruption is very acute and painful, cover these compresses with an ice-bag.

H. HAHN, M.D.

HASTINGS, MINN.

#### PERMANGANATE OF POTASSIUM AS AN EMMENAGOGUE.

To the Editors of the THERAPEUTIC GAZETTE :

GENTLEMEN :—I was greatly pleased with your leading article with the above heading. The views therein expressed coincide with my experience.

On reading the paper by Drs. Ringer and Murrell on manganese in the treatment of amenorrhœa (London *Lancet*, January 6, 1883), I at once wrote to my wholesale druggist for a supply of pills, each containing two grains of the permanganate salt. I have used the drug in scores of cases, both in my private and hospital practice, with the result that I have not seen a single case where I could feel that the slightest benefit had accrued, although the drug in some cases had been persevered with for weeks.

Thus I have been led to doubt the therapeutic value of the drug in this disease. This I have already expressed to several medical friends, who have assured me of good results by its use.

I agree with you that we allow our failures too easily to drop out of sight ; do we not learn more from them than from our successes ? I hope, now that you have opened your columns to your readers for their expression, we may hear both sides of the question, and the therapeutic value of the salts of manganese be placed on a firm basis.

J. FLETCHER HORNE, F.R.C.S., ED.

BARNSELY, ENGLAND, July 12, 1886.

#### Notes and Queries.

##### HYOSCYAMUS IN HICCOUGH.

To the Editors of the THERAPEUTIC GAZETTE :

GENTLEMEN :—A short time ago I wrote to you in regard to hyoscyamus as a remedy in singultus, and I can now report another case cured with the extract. Last week I had a

case of a man who contracted hiccough while attending to his business, and had been suffering two days with it when I saw him. At the time I had no hyoscyamus with me, and prescribed an antispasmodic remedy, but it did no good. On the next day I saw him again, when he was in bed with high fever and hiccoughing every minute or oftener. I rolled out half a dozen pills of the ext. hyoscyamus, gave one, and ordered another to be given in two hours if necessary, and a third in three hours if required. The second checked the trouble considerably, and the third pill stopped it permanently.

Very respectfully,

J. A. CULLUM, M.D.

COTTONPORT, LA., July 15, 1886.

---

*POISONING BY THE LOCAL USE OF  
BELLADONNA OINTMENT.*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—By reading the cases of belladonna-poisoning as reported on pages 313 of the GAZETTE for 1885 and 305 for 1886, three cases that I have seen in my practice in the last eight years have been brought to my mind.

CASE I.—A man, aged about 30, was suffering with dorsal neuralgia. I applied a plaster of belladonna ointment, and it gave him ease in two hours, but in four hours he complained of a choking sensation, his pupils were dilated, face flushed, tongue dry, and pulse rapid. I removed the plaster, had the place well washed, gave opium, and he was all right next day. The skin was not broken anywhere about the location of the plaster.

CASE II.—A lady, æt. 18; tedious labor; water had escaped early, and the os was small and contracted. I took ext. bellad., gr. lx; adeps, ʒi; rubbed them well together; applied the ointment to the cervix on cotton. In one hour my patient complained of choking, face became red, and shortly all the pains ceased. I removed the cotton, gave opium, and, after two hours' rest, labor was completed without any after-trouble.

CASE III.—Lady, æt. 24, the wife of a physician, was under my treatment for vaginismus. I used ext. bellad., gr. xl; sulphate morphine, gr. vi; adeps, ʒss; rubbed this well together, applied it on lint to the vagina, and, after two days' use of it, she began to choke, face got red, and, in short, showed the toxic effect of the drug. But on ceasing the use of it she was well every way, both of the poisoning and vaginismus, and has had no

return of the trouble, and in two days she showed signs of belladonna-poisoning, dry throat, dilated pupils, flushed face; but, after ceasing to use the drug, she was well of both the vaginismus and poisoning.

The last two cases were of much interest to me, as I have never seen anything said about the danger of using belladonna ointment in obstetrics.

Professors Stillé and Maisch say something about poisoning by the ointment being applied to the surface of the body where the skin is broken.

If any of your readers have met with any ill effects of the drug in obstetric practice, I shall be glad to see their reports in the GAZETTE.

Very respectfully,

CHEVES BEVILL, M.D.

WINFIELD, ARKANSAS.

---

*SUPPRESSION OF PAIN IN LABOR BY THE  
LOCAL APPLICATION OF COCAINE.*

An American surgeon, Dr. William M. Polk, was the first to make any report regarding the use of cocaine in operations upon the female genital organs. We believe also that an American obstetrician first reported upon the use of cocaine in labor.

This is denied, however, by DR. M. S. JEANNEL, who, in an article entitled "The Suppression of Pain in Labor by Local Applications of Cocaine," claims that the idea is essentially French, and was first carried out by MM. Doléris and Dubois. These gentlemen, on January 17, 1885, announced that they had applied cocaine locally in eight cases of labor, and in six of them had observed great relief. In September, 1885, Dr. George H. A. Dabbs related his experiences, which were of a similar character, and affirmed that, thanks to cocaine, women could bear children nowadays with very little pain.

Dr. Jeannel (*loc. cit.*) records his observations made during the past year in La Maternité de l'Hôtel Dieu, Saint Eloi. He first applied the cocaine in the form of an ointment with vaseline. He got no results, partly because the vaseline is not absorbed, but mainly, as he believes, because corrosive sublimate injections were made, which drug decomposes the cocaine,—a fact worthy to be borne in mind. Aqueous solutions were then employed, and it was found that a five per cent. solution was sufficiently strong. In the first stage of labor a speculum was used, and the solution painted over the neck and vagina, or

a tampon, saturated with the solution, may be introduced. In the second stage the tampon is introduced directly, without the aid of the speculum, and the liquid should also be carefully applied over the vulva. The operation must be repeated several times.

The pains of labor are due to the following causes, according to Professor Doléris :

First, the muscular contraction of the uterine walls. The pains from this source are usually slight, and cannot be affected by cocaine.

Second, pains are produced by the dilatation of the neck and of the vaginal walls, the nerves of those parts being pressed upon and torn. These pains are relieved to a remarkable degree in many cases by cocaine.

Third, pains of an acute and severe character result from pressure of the child upon the nerve-trunks of the pelvis. Cocaine is powerless to relieve these.

Fourth, some pain is felt from the stretching of and pressure on the mucous membrane. This is suppressed by cocaine.

Fifth, most atrocious pains are produced in the expulsion of the head by the stretching of the vulva and perineum. These, also, according to Doléris and Jeannel, are relieved by cocaine.

The total result of the analgesic application seems to be that in most cases the patient feels but slight pain in the pelvis, and only complains of a dull pain above the pelvis, and pains in the loins.

It yet remains to determine whether the amount of cocaine used is ever sufficient to cause constitutional effects, or to affect the normal contractions of the uterus.

It appears very certain, so far, that cocaine is not so effective or convenient as chloroform, and its claim for adoption must be based on its greater safety and absence of any bad after-effects.

At present the most satisfactory use for cocaine at the time of labor is probably in cases of lacerated perineum. Here a hypodermic injection of a few drops allows the immediate and painless suture of the parts.—*The Medical Record*, July 3, 1886.

#### THE THERAPEUTIC USES OF CUS.

In looking over the files of our esteemed contemporary, the *Dublin Journal of Medical Science*, for another purpose, we have recently noticed an article on "Cus," commending it as a reliable tænicide, with remarks as to the

method of preparation that yields the most forcible product.

We have no doubt it has been used in this country by patients affected by parasites ; in fact, its association with helminthiasis is, to the minds of many, quite natural, but its employment certainly has not been restricted to that or any other special field. The native product, *C. Americana*, is said to embrace a large number of varieties, and to attain a greater exuberance of development than its congeners of any other clime. In the mining regions of the Rocky Mountains and the Pacific coast, we find the *C. occidentalis*, a variegated and particularly florid specimen. It is used in large quantities, and seems to be applicable to all conditions, much like quinine in the South or whiskey in New York. It is not, however, incompatible with the latter drug. The dose varies greatly. It is usually repeated p. r. n., although we are bound to say that its effect is entirely incommensurate with the popularity of the agent.

The philological reflection, which comes late in the reading of the article in question, that possibly our contemporary may have had reference to the diversely-spelled *koussou* (*brayera*, U. S. P.), would, of course, vitiate the above description. But, in view of the much greater importance in this country of the agent we have described, we prefer to accept the more obvious interpretation.—*Boston Med. and Surg. Journ.*, June 30, 1886.

#### OSMATE OF POTASSIUM.

MERCK, of Darmstadt, has prepared the osmate of potassium to obviate the use of osmic acid, which is so irritating to the respiratory organs and so hygroscopic. The potassium compound is said by Wildermuth to have proved beneficial in some cases of epilepsy, the daily dose being one dozen pills, each containing  $\frac{1}{4}$  of a grain in combination or alternation with bromide of potassium. A one per cent. solution of the potassic osmate has also been recommended in the treatment of goitre, neuralgia, tumors, and other diseases.—*Lancet*, June 5, 1886.

#### ALUMINIUM ACETATE AS AN ANTISEPTIC.

In the November number of the *GAZETTE* we published a paper by DR. ROSE as to the value of aluminium acetate as an antiseptic: the statements which he there made as to the sufficient and reliable germicidal and an-

tiseptic properties of aluminium acetate have been confirmed by DR. A. L. CLARK (*Chicago Med. Times*, June, 1885), who found that it was perfectly able to prevent putrefaction, and in several cases where it was used as a dressing for lacerated wounds it served to preserve the wounds antiseptic.

#### THE PHYSIOLOGY OF FATIGUE.

Alpine and athletic clubs are hardly less interested than the physiologist in the elaborate series of experiments recently made by Drs. Mosso and MAGGIORA on the laws of fatigue, and described by them in the monograph just presented to the Accademia dei Lincei. These accomplished inquirers began their operations by constructing a mechanism by means of which they could observe the variations of the efforts put forth by a finger in lifting a weight until entire exhaustion had set in. The mechanism was then readjusted in such a way that the operator's whole arm remained motionless, with the one exception of the muscle corresponding to the finger in action. The variations of the muscular effort were graphically traced on blackened paper, and from these tracings it resulted that every individual under experiment gave a special characteristic trace, which at once distinguished his effort from those of the others. Resistance to fatigue was then seen to be different at different hours of the day, and the influence of food upon it was also found to vary. Further, a special study was made of the important problem of the disposing of pauses, so as to make the outlay of force as economical and as effective as possible. The practical importance of these inductions to pedestrians or soldiers on the march is obvious. According to Drs. Mosso and Maggiora, the resulting fatigue is twofold,—the fatigue of nervous failure and the fatigue of muscular failure. In certain cases, the fatigue comes from the collapse of the muscular tissue only, while in others it happens that the brain suspends the supplies necessary to keep the muscles active. Some experiments showed that if a fatigued finger bore a weight with difficulty, the moment the weight was withdrawn the finger recoiled backwards with force,—a proof that while the muscular energy had run out, the nervous energy was striving to compensate it by imposing on the muscle an effort much stronger than necessary. Professors Mosso and Maggiora next describe a series of experiments on the influence of the

weight to be lifted, as well as on that of anæmia. To ascertain the latter, they constricted the arteries of the arm under experiment by impeding the afflux of blood, or they rendered it totally bloodless by encasing it in strong ligatures of gutta-percha. In this condition the muscle was found capable of continuous effort, but only through nervous excitation, while it was observed in what manner the muscular energy revived gradually as the blood returned into the arm. The effects of fasting, and the duration of time that must elapse after the taking of food to re-establish the conditions of normal muscular labor, formed a further series of investigations, in connection with which there was determined the influence of respiration and of those processes of training whereby the organism is inured to bear the heaviest fatigue, as in the case of Alpinists before undertaking a formidable ascent. Finally, Drs. Mosso and Maggiora overhaul afresh the familiar experiments as to what and how great is the influence of certain aliments in the production of labor, whether their action is beneficial or not, confirming by novel methods the induction that alcohol, so far from augmenting muscular energy, positively diminishes it, while other ingesta increase the output of work by substantial reinforcement of the organism.—*Lancet*, June 26, 1886.

#### COCAINE IN MERCURIAL STOMATITIS.

BOCKHART recommends in the *Monatshefte für Praktische Dermatologie*, No. 2, 1886, cocaine as an efficient remedy for the painful tumefaction of the gums occasionally observed in the course of a mercurial treatment. A ten to twenty per cent. solution of the hydrochlorate of cocaine is to be brushed over the affected part several minutes before meal-time. If the mucous membranes present (mercurial) ulcers, a five per cent. solution of cocaine suffices. The brush is to be disinfected with carbolic acid after having been used, as the solution would otherwise soon undergo decomposition through the agency of the bacteria of the mouth.

#### WASHING OUT THE STOMACH OF LUNATICS WHO REFUSE FOOD.

DR. E. REGIS, having been asked to give the members of the Bordeaux Medical Society some account of the progress which has been made during recent years in the treat-

ment of insanity, selected a single practical point of great importance, namely, refusal of food, or, as he called it, sitiophobia. This, he remarked, is very frequent in asylums; it is but a symptom only, or rather a complication, not a disease of itself. It is especially common among female patients, and is the rule among subjects of lypemania, or melancholy. It is sometimes seen in mania and alcoholic cases; and, though more rare in general paralysis, is still seen in the depressive or non-grandiose form, the patients believing that they have no stomach, intestines, or mouth, and that therefore they are incapacitated for eating. In patients who believe themselves to be undergoing persecution, and in religious and mystical mania, sitiophobia is very common. The gravity of the condition is not equal in all classes of cases, but it is always to be looked upon as of serious import. In melancholy, it is certainly possible for it in tedious cases to bring on a fatal result by inanition. With regard to the treatment and the manner of carrying on alimentation by force, the speaker reviewed the various plans that had been adopted by Marcé, Esquirol, Baillarger, Leuret, Marchant, Blanche, Farabœuf, Billod, Ritti, Sizaret, and F. Raspail, stating that his own preference was for a simple nasal sound of soft rubber, lubricated with vaseline instead of with oil. In addition to forced feeding, M. Régis has, for some years past, been in the habit of washing out the stomach, especially in cases where there were signs of gastric catarrh, which is very frequent among lunatics. For this purpose he used the double current stomach-pump of Kussmaul, and obtained most marked success, which encouraged other physicians to follow his example, with the result of obtaining similar favorable changes in the patients. Of late he has altogether discarded the stomach-pump for a simple Faucher's tube; and he is convinced that, if the washing out of the stomach were to become universal in this condition, a large number of such patients would be very much improved. Even in the case of non-sitiophobic melancholics, this treatment would, he thinks, prove very beneficial.—*Brit. Med. Journ.*, July 3, 1886.

#### POISONING BY SORREL.

An extremely curious case of poisoning is reported from Birmingham. A few days since, a boy, 5 years of age, ate a quantity of sorrel-leaves, which he gathered at the back of his father's house. During the fol-

lowing night he appears to have complained of giddiness and intense thirst, and to assuage the latter he got out of bed and drank some soapy water which happened to be in a jug on the dressing-table. Shortly afterwards he became unconscious, and died. The medical evidence attributed death to oxalic acid poisoning, resulting from the action of the soap on the green sorrel. This wild plant, which is well known to contain a noticeable quantity of the oxalates, is a favorite with country children, from its pleasant acidulous taste, but it is quite new to find it capable of toxic effects. The theory put forward is certainly ingenious, and, if correct, it does credit to the acumen of the medical witness. None of the works on medical jurisprudence record any deaths from the ingestion of the raw plant, and abroad the cultivated plant is an important and largely-consumed article of food, without producing any untoward symptoms. It is credited with certain aphrodisiac properties, which, when manifested, are probably due to the irritation of the genito-urinary tract produced by undue acidity of the urine.

It would be interesting to have the details of the case, so that one might know on what grounds death was ascribed to the effect of oxalic acid poisoning. Perhaps some of our readers may be enabled to furnish details of similar cases, with some explanation of the alleged action of an alkali in separating the oxalic acid in such a way and to such an extent as to lead to a fatal result. There are plenty of plants capable of causing death which seem to attract children's attention, and it is difficult to avoid a suspicion that the sorrel may not have been alone in producing the symptoms referred to. Of course, from a legal point of view, the exact cause of death is tolerably indifferent, but it is quite otherwise from a medical stand-point, since treatment would naturally require to be adapted to the particular toxic agent which had found its way into the omnivorous stomach of the juvenile prowler.—*Med. Press*, June 23, 1886.

#### FAVORABLE RESULTS OF PREVENTIVE VACCINATION AGAINST MILZBRAND (SPLENIC FEVER).

The principle of preventive vaccination, as first proposed by Jenner and recently extended by Pasteur and other microbio-pathologists, continues to be productive of practical results which justify no small anticipations. As we learn from a communication of the state veterinary surgeon of Cherson, Russia,

DR. KRAJEWSKI, to the *Centralblatt für die Medicinischen Wissenschaften* (No. 1, 1886), Prof. Zenkowski vaccinated last summer 1333 sheep, of which, after the first vaccination, 1.6 per cent., and, after a second, 0.3 per cent., only perished. The importance of these results is clear enough, when we learn that the usual annual losses from anthrax in Russia are as high as twelve to twenty per cent.

#### ETHOXYCAFFEINE.

This body is caffeine in which one atom of hydrogen is replaced by the group  $C_2H_5O$ . Alkalies precipitate its salts from their solutions. Hypodermic injections in rabbits gave indications of a narcotic action. M. Dujardin-Beaumetz has administered this agent in cases of severe headache, and with beneficial results. Its insolubility is an objection, as is also its tendency, with other allied bodies, to cause gastric symptoms. Most of these difficulties are overcome by dissolving the drug in salicylate of sodium and adding some carminatives. The largest dose given was 25 centigrammes. Guarana and Paullinia owe their value in megrim to their containing caffeine.—*Lancet*, July 3, 1886.

#### PILIGANINE.

M. ADRIAN has discovered a new alkaloid in lycopodium Saussures. It has an alkaline reaction, and emits white vapors, like ammonia, in the presence of hydrochloric acid. It causes powerful emesis and catharsis.—*Lancet*, July 3, 1886.

#### THE DANGER OF SYNCOPE IN HOT BATHS.

It is surprising that deaths by syncope during the use of hot baths are not more common than the coroner's court returns would show them to be. The peril of faintness by the mere determination of blood to the surface of the body, thus quickly depriving the heart of its usual normal support and stimulus, is very great. In cases of muscular weakness of the heart this danger must be imminent whenever the "hot" or even the "warm" bath is used. Apart from this obvious risk, however, there is always the possibility that in weakly or too impressionable states of the nervous system the peripheral stimulation produced by the application of heat to the whole of the cutaneous extremities of the afferent nerves may so act on the centres as to

arrest the evolution of energy by an inhibitory influence. It is doubtful whether we lay enough stress on this consideration when prescribing the use of such external agents as act on large areas of surface and strongly impress the nerves there commencing. We know how burns of even moderate severity may kill by the impression they produce on the centres of vitality from the periphery. There is much to learn in regard to the nature and extent of the central effects which may be thus caused. Whether for good or evil, the application of heat or cold to the whole surface is a potent measure, and one that ought not to be recklessly resorted to, more especially in cases of great susceptibility, involving such excitability of the nervous centres as often coexists with fairly good health in a weakly body.—*Lancet*, July 3, 1886.

#### THE BACTERIA OF GRANULATIONS.

At a recent meeting of the Paris Surgical Society, M. PONCET stated that the bacteria of granulations were studied in 1881 by Sattler. M. Poncet detected in an eye enucleated by M. Dehenne the presence of a micrococcus in the interior and exterior of the granular cells. This investigator also found it in the membrane of Descemet, and in the iris. M. Poncet considered it possible that the micrococci had penetrated into the anterior chamber in consequence of an incision, for iridectomy had evidently been performed. M. Poncet showed drawings representing the position of the micrococcus in the granulation. Sattler's statement that this micrococcus was analogous to that of gonorrhœa, M. Poncet considered to be erroneous. He declares that the former is much larger.—*British Medical Journal*, July 3, 1886.

#### ELECTION OF DR. BROWN-SÉQUARD TO THE ACADEMY OF SCIENCES.

According to the Paris correspondent of the *Lancet* (June 26, 1886) the portals of the Paris Academy of Sciences have at last been opened to Dr. Brown-Séquard, as he was elected member at its last meeting on Monday, in the Section of Medicine and Surgery. The eminent biologist was elected by a large majority, and the victory was the more creditable as the competitors of Dr. Brown-Séquard were all men of note, in proof of which statement it is only necessary to mention the names of Germain-Sée, Bouchard, Jaccoud, Hayem, and Richet.

## Original Communications.

### A CONTRIBUTION TO OUR KNOWLEDGE OF FEVER, AND THE AGENTS WHICH PRODUCE OR ARREST IT.

BY DRs. H. C. WOOD, E. T. REICHERT, AND HOBART A. HARE.

#### INTRODUCTION.

THIS research grows out of a statement, which was some time ago made in a German journal, that pepsin injected into the blood would produce fever, and is accompanied by very little discussion of the literature of the subject, because the field which it especially occupies has previously received

little attention. The ultimate object of the research has been to throw light upon the nature of fever and upon the relation of the febrile reactions of the body to organic substances. Of course the literature of fever is enormous; but to have entered upon any general study of it would have carried us far beyond our present intention.

The calorimeter which we have used in these experiments is in most respects similar to that employed by Dr. H. C. Wood in his research on fever, but differs in being designed to take out all the heat absorbed by the air after its entrance into the inner box, and thus to avoid the loss of time in observation and calculation which is involved in Dr. Wood's plan of measuring the amount of

air used and its temperature before and after its exit, and then calculating the heat abstracted by such air. Metal tubes are, in our calorimeter, coiled in the space between the two boxes, where the water is during the working of the instrument; and, as the temperature of the water is kept a little lower than that of the air, any heat absorbed in the central box by the air is given up to the water. In order to test the accuracy of this calorimeter, we devised an arrangement by means of which known quantities of the city gas could be burnt in the inner box with the apparatus set up and the air-pumps at work. Under such circumstances, we find that the water in the outer chamber rises with remarkable regularity with the combustion of equal quantities of gas. We believe, therefore, that the calorimeter used at a temperature of three or four degrees below that of the external air is an instrument of precision, provided that great care be exercised to see that, at the beginning of the experiment, the calorimeter itself is of uniform temperature throughout, and that the water in it is thoroughly stirred from time to time, especially when the temperature is about to be taken.

#### PART I.—FEVER-PRODUCING AGENTS.

In studying the action of pepsin upon the animal organism, when introduced directly into the blood, we have made use of an article furnished by Hance Brothers & White, of Philadelphia, and also of the commercial "soluble pepsin" sold by Fairchild Brothers, of New York. The symptoms produced have been uniform, but varying according to the amount and to the strength of the pepsin employed; the pepsin of the same manufacturer varying in its activity.

In the dog, when pepsin, rubbed up with water but not filtered, is injected into the blood, death from failure of the circulation may result at once if the dose has been large enough, as is shown by the following experiment:

##### *Experiment 1.*—A very small dog.

Time. M. S.	Pulse.	Art. Press. Mm. mercury.	Remarks.
0.	230	140-150	
1.	.....	.....	Began injection of Fairchild's pepsin, 1 gramme in solution; only about half of it was thrown into jugular vein.
1.15	235	150-160	Injection finished.
1.24	.....	80	Pulse cannot be counted, so small. Respirations full and deep.
1.30	.....	75	No pulse. Apparatus so arranged in this experiment that Zero of arterial pressure is 75.

Time. M. S.	Pulse.	Art. Press. Mm. mercury.	Remarks.
1.33	.....	.....	Still occasional deep respirations, but no pulse.

The respiration is also profoundly affected. At first it is excessively hurried, and becomes very full and struggling. There are often at this time violent convulsions. The respiration after a shorter or a longer period of stormy rapidity becomes slow, it may be with great suddenness, and then is abolished altogether. These changes may, especially in the rabbit, dominate the depression in the circulation, and produce a vaso-motor spasm with great rise of the arterial pressure, even at a time when the smallness of the pulse shows the still existing cardiac weakness. As an example of this we give the following experiment:

##### *Experiment 2.*—Full-grown rabbit.

Time. M. S.	Pulse.	Art. Press.	Resp.	Remarks.
1.00	230	120	90	Very slow injection of 1 c.c. of water, containing 1 grain Fairchild's pepsin, began into jugular vein.
1.15	250	102	120	
1.24	.....	78	132	Injection finished.
1.30	240	84	210	Directly after injections ceased violent respiratory struggles came on.
1.45	160	60	212	Pulse scarcely to be made out on tracing.
1.50	?	56	180	Pulse not perceptible.
1.57	.....	120	185	Pulse not perceptible.
2.04	.....	.....	.....	Respiration stopped; general convulsions.
2.09	240?	214	none.	Pulse so small and irregular cannot be fairly counted.
2.22	.....	.....	.....	One deep respiration, very full and slow.
2.28	.....	.....	.....	Convulsions continue: during one the canula torn out of artery.
2.30	.....	.....	210	Respirations small, irregular.
2.40	.....	.....	.....	Respirations going on with regularity.

Animal died about fifteen minutes later. A spectroscopic examination of blood drawn just before death showed normal oxyhæmoglobin.

The disturbance of respiration and the convulsions which follow the injection of pepsin are, we believe, due to plugging up by particles of the pepsin of the blood-vessels of the medulla. When Fairchild's pepsin is used they are exceedingly severe, with the article prepared by Hance Brothers & White they are much less pronounced. Even when rubbed with water most carefully, Fairchild's pepsin gives a mixture containing numerous coarse particles, whilst the other pepsin is an almost impalpable powder. Further, we have produced similar disturbances of respiration by injecting very finely-powdered dried meat into the jugular vein, as in the following experiment:

*Experiment 3.—Rabbit.*

Time. M. S.	Art. Press.	Resp.	Remarks.
0.00	130	84	
0.01	.....	.....	Injection begun of a very small quantity, a grain or two, of meat.
0.09	100	.....	Injection finished. Respiration just stopped.
0.13	75	.....	Respirations renewed.
0.18	170	210	Very irregular and short respirations, convulsive tremors.
0.29	170	.....	Respirations practically none.
0.35	85	.....	Respirations very shallow and irregular.
1.10	100	.....	Only one respiration in thirty seconds.

No attempt at respiration after this, although pressure kept up for one-half minute.

The fall of arterial pressure which follows an injection of pepsin we believe to be due to an influence exerted upon the heart. In Experiment 2 the sudden rise of pressure from 56 to 214, which was produced by arrest of respiration at a time when the pressure had fallen from 120 to 156, shows that the vaso-motor system is not affected until very late in the poisoning.

When the amount of solid pepsin introduced at one time is not large enough to produce such profound result as those we have chronicled, but still is sufficient to cause death in a very short time, the animal becomes quiet and excessively weak; the bodily temperature falls, and death occurs in general asthenia. When small amounts of the pepsin are employed, there may be a decided shivering fit, lasting fifteen minutes to half an hour, in which the animal tries to get near the fire, and seems to be suffering from a sensation of coldness. This condition is succeeded by fever, lasting some hours, which, on its gradual subsidence, leaves the animal in apparent good health; or, if the dose has been properly proportioned, hæmaturia and excessive purging come on, and the animal dies in collapse.

Our next efforts were directed towards finding out what it is in commercial pepsin which produces the symptoms. The hæmaturia we at first supposed was due to a digestion or destruction of the blood-corpuscles by the ferment. But we have experimentally determined that in the blood of the poisoned animal the spectrum is that of normal oxyhæmoglobin, and that when blood is digested with pepsin outside of the body, at a temperature of 100° F., for twelve hours, there is no alteration of the spectrum, and no disappearance of the red disks or appearance of their debris. Comparative studies made with Mannassein's blood-counting apparatus of the blood-cor-

puscles, before and after the digestion of the blood with the pepsin, and careful microscopical examinations failed to show any alterations in the number or character of the corpuscles.

When the pepsin powder was injected into the blood death was produced by a few grammes, but if the pepsin were thoroughly rubbed up with water and filtered, the filtrate, which, of course, contains the active pepsin, could be injected, in quantities representing twenty grammes of the commercial pepsin, into the jugular vein of small dogs, without producing fatal results. We have also never been able to cause bloody diarrhoea or hæmaturia with this solution, and we therefore believe that the hæmaturia and bloody flux are the results of infarctions in the kidneys and intestinal walls, such infarcts being due to the minute solid particles of the commercial pepsin.

In order to determine whether it is the soluble or insoluble portions of commercial pepsin which produce the fall of arterial pressure, two experiments were made with a clear liquid obtained by rubbing up Fairchild's pepsin in water, and filtering through a double filter. The experiments are as follows:

*Experiment 5.—Very old dog; weight, 12 pounds.*

Time. M. S.	Pulse.	Art. Press.	Remarks.
0.	135	140-160	
1.	130	140-160	Began injection of 10 c.c. saturated solution.
1.15	208	110-115	Injection finished.
1.10	300	75-80	
1.50	300	80-90	Injected 10 c.c. as before.
2.	330	60-70	
5.	236	135	

*Experiment 6.—Very old dog; weight, 20 pounds.*

Time. H. M. S.	Pulse.	Art. Press.	Remarks.
12.10	216	140-150	Injected 12 c.c.
12.10.10	.....	.....	Injection finished.
12.10.10	300	70-100	
12.10.25	.....	75-90	
12.10.50	.....	80-100	
12.11.30	.....	120-180	
12.30	140	140-165	Injected 1 gramme of Fairchild's pepsin rubbed up in water.
12.30.05	192	98-105	
12.33.30	192	120-130	

These experiments indicate that the depression of the arterial circulation, caused by an injection of commercial pepsin, is largely

the result of the mechanical action of its insoluble particles. A hasty large injection of filtrate does produce a temporary fall of arterial pressure, but this is speedily recovered from, and, in truth, does not occur when the injection is practised with only moderate rapidity, unless very large amounts of the filtrate be used. At the same time, when solid pepsin is used, the effect upon the circulation varies greatly, and embolism of the coronary artery of course suggests itself as a plausible explanation of the cardiac failure when the action is excessive.

The pepsin fever is produced by the injection of the filtrate from commercial pepsin, as is shown by the following experiments, which have been, we may add, frequently repeated with consonant results :

*Experiment 7.*—October 20 ; carriage-dog ; weight, 23 pounds.

Time. M. S.	Rec. temp.	Remarks.
9.20	104.6°	Injected 25 c.c. of a strong filtrate from concentrated pepsin.
12.30	105.4°	Vomited several times before twelve o'clock.
1.45	106°	
3.	104.5°	

*Experiment 8.*—October 24.

Time. M. S.	Rec. temp.	Remarks.
9.50	104.3°	Filtrate from 7.5 grammes of concentrated pepsin.
10.15	.....	Shivering fit.
2.	107.3°	

*Experiment 9.*—October 26 ; small yellow pup ; weight, 10.5 pounds.

Time. M. S.	Rec. temp.	Remarks.
11.50	104.2°	Injected 40 c.c. of filtrate from 11 grammes of Fairchild's pepsin.
12.45	107.4°	Dog quiet.
1.45	108.3°	

*Experiment 10.*—October 26 ; dog.

Time. M. S.	Rec. temp.	Remarks.
11.15	104.4°	Injected filtrate from 11 grms. of commercial pepsin.
1.	106.8°	
1.40	105.4°	
3.15	104.2°	

The rapid development of fever after pepsin injections, and the absence of any signs of a catalytic action in the blood, suggested to us that it is not the pepsin itself, but something contained in it, which causes the fever.

We therefore made the following experiments, in which the ferment was destroyed by boiling :

*Experiment 12.*—October 29 ; yellow dog ; weight, 16 pounds.

Time. M. S.	Rec. temp.	Remarks.
10.45	104.4°	Injected 110 c.c. of filtrate from 11 grammes of concentrated pepsin which had been boiled for ten minutes.
11.50	104.4°	
3.45	106.3°	

*Experiment 13.*—October 30 ; brown bitch pup.

Time. M. S.	Rec. temp.	Remarks.
9.25	103.7°	Injected filtrate from 12 grms. of pepsin which had been boiled for ten minutes.
11.4	108.4°	
1.	108.8°	
2.	107°	

These experiments have been repeated a large number of times with uniform results. They undoubtedly prove that the pyrogenic agent in commercial pepsin is not the pepsin itself, but some contaminating principle.

Having determined that the poisonous principle of commercial pepsin is not the ferment, it was our next endeavor to discover, if possible, the nature of the poison.

On adding to the boiled and filtered solution of pepsin an excess of strong alcohol a copious precipitate was obtained, which, when dry, yielded an amorphous substance entirely soluble in water. Experiments were then made with this material to determine its physiological properties. The principle itself, as will hereafter be shown, is of the nature of a peptone. The experiments are as follows :

*Experiment 14.*—Dog ; weight about 10 pounds.

Time. M. S.	Remarks.
10.05.	Rectal temperature 105.8°.
10.10.	Injection into the jugular of 0.5 gramme of peptone.*
10.15.	Dog excessively weak, apparently dying.
10.45.	Rectal temperature 103.5° ; the dog still very sick and apparently dying.
11.	Dog improving very decidedly.
11.10.	Improvement still continues.

\* One ounce of Hance Brothers & White's concentrated pepsin, which we understand contains fifty per cent. of sugar of milk, yielded about ten grains of the dried peptone. If dried at too high a heat, a portion of this peptone becomes insoluble in water, and the toxic power is correspondingly diminished.

Time. M. S.	Remarks.
11.45.	Dog worse; unable to stand; has passed a little bloody serum from the bowels. There appears to be slight dyspnoea. Rectal temperature 98.1°.
11.55.	Dog dead.

*Experiment 15.—Dog.*

Time. M. S.	Remarks.
10.30.	Rectal temperature 106.5°; injected 0.11 grm. of peptone which had been digested for ten days in absolute alcohol and then dried. This peptone was one-sixth of that which had been obtained from 20 grammes of concentrated pepsin, and therefore represented about 3½ grammes of pepsin.
10.35.	Dog has been vomiting; is very weak, and can scarcely walk; respiration deep.
11.38.	The dog seems to be dying; has Cheyne-Stokes's respiration.
11.05.	Rectal temperature 106.9°; the dog much improved; is breathing normally.
11.45.	Dog is quiet, but not so depressed; temperature 107.9°.
12.45.	Rectal temperature 107.9°.
2.45.	Rectal temperature 107.9°.

*Experiment 16.—Weight of dog 42.5 pounds.*

Time. M. S.	Drug.	Art. Press.	Pulse.	Rec. temp.	Remarks.
12.21	.....	190-210	144		
12.21.10	Peptone	180-200	150		
12.21.20	0.05 grm.	166-180	300		
12.27	.....	140-160	138	.....	Dog quiet.
11.29	.....	160-168	144	.....	Breathing labored, respiration hurried.
12.32	.....	170-174	132	.....	Absolutely quiet.
12.35	.....	170	138		
12.35.10	0.15 grm.	170	120	.....	Injection begun.
12.35.20	.....	170-190	168		
12.35.30	.....	194-174	132	.....	Violent breathing.
12.35.50	.....	184	120	.....	Injection ended.
12.40	0.2 grm.	184-168	.....	.....	Injection begun.
12.40.10	.....	192	114		
12.40.50	.....	180-190	.....	.....	Injection ended.

12.54	.....	220-200	78		
12.54.10	.....	210-190	78	106.2	
1.02	0.2 grm.	190-202	.....	106.2	Injection begun.
1.01	.....	196	72	.....	Injection ended.
1.15	.....	180-190	108	105.8	
1.25	.....	.....	.....	105.5	Blood coagulating well. Dog killed.

These experiments prove that the material which we obtain by the precipitation of a boiled and filtered solution of commercial pepsin is the pyrogenic poisonous principle of the pepsin; and, also, that when this principle is injected into the blood in certain amount it produces very distinct fever, without a pronounced effect upon the arterial pressure; but that when larger quantities are employed a condition of excessive asthenia is at once produced, accompanied by a very marked

fall of the bodily temperature, and soon ending in death.

We have determined that the pyrogenic principle of commercial pepsin is of the nature of a peptone. It yields a perfectly clear solution with water, which has a neutral reaction. The peptone gives the following reactions:

Boiling, no effect.

Proteid color-reactions. — Xanthoproteic, good.  
Millon's reagent, good.  
Biuret's, good.

Mercuric chloride, good.

Ferric chloride, none.

Cupric sulphate, none.

Neutral lead-acetate, good.

Tannic acid, good.

Absolute alcohol, a precipitate soluble in water.

Strong nitric acid, none.

Strong acetic acid, none.

Strong hydrochloric acid, none.

This peptone also gives a very slight precipitate with ferrocyanide of potassium and strong or dilute acetic acid. And thus has some resemblance to the  $\alpha$  peptone of Professor Meissner, from which it differs in yielding a much smaller amount of precipitate with reagents just mentioned. For it we propose the name *pepsin-peptone*.

It has been suggested by a friend that the poisonous principle of commercial pepsin is allied to sepsin, obtained in 1868 by Drs. E. Bergmann and O. Schmiedeberg (*Centralbl. für Med. Wissens.*, 1868, 497) by a complicated process from decayed yeast. The work of these investigators was gone over by Dr. Anton Schmidt (Thesis, *Das Sepsin*, Dorpat, 1869), who obtained the sepsin as a pure snow-white crystallized substance, of which 0.025 gramme was sufficient to kill a very large dog. It is plain that sepsin is of the nature of a ptomaine, and that it differs absolutely from the substance which we obtained in that it is soluble in alcohol, whilst pepsin-peptone was procured by precipitating it from its watery solution by the addition of alcohol. Pepsin-peptone also differs in a similar way from the poisonous principle which Professor L. Brieger (*Zeits. f. Physiologie Chemie*, vii. p. 277) obtained from ordinary peptone by extraction with alcohol. It is of course very probable that Brieger's extract was of the nature of a ptomaine.

The results of Brieger suggest the possibility that pepsin-peptone owes its poisonous prop-

erties to the presence in it of a contamination. To discover if possible such contaminating substance, we digested a specimen of the pepsin-peptone with amyl alcohol, filtered, and evaporated in a capsule to dryness, when a mere trace was left. On similar treatment with chloroform, petroleum ether, amyl alcohol, sulphuric ether, nothing was dissolved. The failure to obtain any organic crystalline principle by these solvents seems to us to prove that the pepsin-peptone which we used is free from ptomaine. That the residue which was left after the evaporation of the ethyl alcohol is not the poisonous principle is shown by the fact that in Experiment No. 15 the pepsin-peptone which was used had been digested for ten days with a great excess of alcohol, which must have removed from it everything soluble in that liquid.

In order, however, to make a further test of the matter, basic acetate of lead was added to the solution of pepsin-peptone in distilled water. A white flocculent precipitate formed, but redissolved upon the addition of more of the basic acetate. To this solution ammonium hydrate was added, and the white precipitate which fell was collected on a filter-paper, washed with water, separated from the filter-paper, and suspended in water. Sulphuretted hydrogen was then passed through the water to precipitate the lead. The sulphide was filtered off, and the filtrate evaporated on the water-bath to dryness. The residue was very small in amount, was not crystalline, and on testing was found to be largely composed of lactose.

The filtrate obtained from the precipitation of the basic acetate of lead by ammonia was warmed, and sulphuretted hydrogen passed through it until all the lead in it was precipitated. The solution was then filtered, and the filtrate evaporated to dryness slowly on a water-bath. A considerable quantity of a brown gummy mass containing minute crystals was obtained. On testing physiologically this mass it was found to be active. Twelve centigrammes of it injected into the jugular vein of a small cat produced a rise of temperature of nearly three degrees.

The crystals obtained in the final product of the studies just reported were believed to be ammoniacal. It is plain that if the peptone itself should come out of this process it would be in the final mass obtained, and that unless the peptone be entirely destroyed this mass would be physiologically active. The fact, therefore, that this mass was active is no evidence whatsoever that the crystals were of

the nature of a ptomaine, or were the original poison.

The method of obtaining the final gummy mass was such as to strongly indicate that the crystals in it were ammonium acetate, formed by the decomposition of the basic acetate of lead by the ammonium hydrate. In order positively to prove this, we added the basic acetate of lead to a fresh solution of pepsin-peptone until a clear liquid was obtained, warmed this liquid, and passed sulphuretted hydrogen through it until no further precipitation occurred, filtered, and evaporated the filtrate to dryness; the gummy mass left contained no crystals. As the process through which the pepsin-peptone was put was identical with that by which the crystals were obtained, except in the addition of ammonium hydrate, it is a necessary inference that these crystals were an ammoniacal salt.

That certain peptones when introduced into the blood act as poisons is not an altogether new idea. In the *Archiv f. Phys.*, 1880, Dr. Adolf Schmidt-Mulheim announced the fact that large quantities of ordinary peptone thrown into the blood of the living animal prevent its coagulation, and, at the same time, lower very greatly the arterial pressure by, as he believes, but does not prove, a direct paralyzing influence upon the walls of the blood-vessels. Along with the fall of the blood-pressure great restlessness appears, soon followed by muscular weakness, and, finally, paralysis of the limbs. In the last stages of the poisoning secretion of urine is arrested and convulsions may occur. Influenced by the statements of Schmidt-Mulheim, M. Winckler, a Bavarian veterinarian, proposes, in the *Archiv f. Wissen und Praktische Thierheilkunde*, 1883, Bd. lx. p. 419, a theory to account for the "subacute cerebritis" frequent among horses in certain parts of Germany.

This disease appears to be closely allied to the so-called *loco* disease which is common in domestic animals in certain districts of the Western United States, and which is usually attributed to one or two species of the genus *Astragalus*. In Germany the affection under consideration is believed to be the result of excessive feeding upon certain leguminous plants, which plants are, however, not poisonous. Parallel to this are the results of experiments which we have made with *Astragalus* sent from the far West, as *loco* or *crazy weed*. The extracts of these plants we found to be entirely inert. Winckler believes and apparently proves that the symptoms of the so-called subacute cerebritis are not the result of

any brain inflammation, but are the outcomes of a constitutional affection. He also believes that the poisonous principle which causes this disease is a peptone formed in the blood by the action upon its fibrin of the ferment which was discovered as an abundant principle in leguminous plants by Gorup-Besanez, who also found that it has the property of forming peptones with fibrin. The theory of Winckler is that when an animal feeds on an excess of these leguminous plants there is sufficient absorption of this ferment to form in the blood a peptone, which is the cause of death. The *Astragalus* of the West is a leguminous plant, and probably contains the ferment of Gorup-Besanez. If the theory of Winckler be correct, the loco disease is probably also a peptone-poisoning. Unfortunately, Mr. Winckler does not prove the truth of his theory. He simply by general considerations renders it probable. As the loco disease is a matter of very great importance to the stock-raising interests of this country, a research should be made upon this point. It would be a very simple matter to determine the truth or falsity of the theory of Winckler.

The importance of the poisonous properties of peptone is much enhanced by the fact that these compounds have been found to be produced in the internal organs during certain diseases. E. Salkowski obtained a peptone from the liver of a patient dead of leucocythemia (*Virchow's Archiv*, 116), an observation which has been confirmed by Bockendal and Landwehr (*Virchow's Archiv*, Bd. lxxxiv. p. 561). Salkowski also found peptone in the spleen, the liver, and the kidneys of a case of acute yellow atrophy of the liver (*Virchow's Archiv*, Bd. lxxxviii. p. 394). Sotnitchewsky (*Zeitsch. für Physiologie Chemie*, Bd. iv. 217) finds that peptone is constantly present in the lungs of persons dead of fibrinous pneumonia; whilst M. Muria (*Virchow's Archiv*, Bd. ci.) asserts that these principles can always be discovered in the viscera of animals killed by phosphorus, and has obtained them in quantities from the liver, spleen, and uterus of patients dead of puerperal fever. Finally, Fischel (*Archiv für Gynakologie*, Bd. xxiv.) finds that the peptones are constantly formed during involution following childbirth.

It is a growing conviction with clinicians that many of the symptoms which accompany various acute constitutional disorders are not produced directly by the germs or other poisonous agents which are the immediate cause of the disease, but are caused by substances which are formed during the vital

processes provoked or altered by the original poison. There has been also a tendency to believe that these secondary poisonous principles are usually of the nature of alkaloids belonging to the so-called class of ptomaines. Our experiments of course do not, in any way, disprove the existence of ptomaines, or their activity for evil. They certainly indicate, however, very strongly that the pyrogenic poisons of these constitutional affections are at least, in some cases, peptones. It has been proven that peptones are pyrogenic agents, and that at least some of them act when present in very small quantities. It has also been proven that peptones are found in the viscera of persons dead of various constitutional disorders, and it is very probable that these peptones during life pass into the blood and exert a powerful febrifacient influence upon the organism.

(To be continued.)

*LANOLIN, A NEW FATTY SUBSTANCE;  
ITS PHYSICAL PROPERTIES AND  
THERAPEUTIC USES.\**

BY PROF. OSCAR LIEBREICH, BERLIN.

AT the present time the object of experimental pharmacology is twofold: on the one hand we have to investigate remedies which have already gained a fixed position in practical medicine, while, on the other hand, we must study products which have been made the subject of experimental and pharmacological inquiry, but which have not yet been tested practically.

It is this experimental pharmacological method which more especially claims my attention, and I am of opinion that it is a most important mode of investigation; at the same time, I readily admit that the results of clinical experience must never be lost sight of.

The principal aim which I have in mind is to make not only abstruse physiological or chemical experiments, but to turn these experiments to account in the light of my pharmacological studies. Even those which appear to have a purely theoretical interest become the origin of practical discoveries.

Pharmacology must unite with all those branches of medicine, and pursue an exact experimental course. There can be no doubt that products obtained by the pharmacological method must inspire more confidence than

\* Read before the British Medical Association at the recent meeting at Brighton, England.

those which are simply introduced by empirics.

There is a great difference between recommending a drug which has been studied from a pharmacological point of view, and only introducing it in order that it may be tried in practice without previous experiments. In the latter case a certain substance is introduced, and the decision on its merits is left to those who try it on their patients and who judge by the results of their statistics.

One of the branches of pharmacology which has been most neglected is that which refers to drugs used in the treatment of skin-diseases.

In consequence of our pathological studies into the nature of diseases, the local treatment has become more and more important.

The method which I have employed, and the substance itself which makes the subject of my paper, are so simple, that I should be unwilling to occupy your time to present to you some important considerations which will have soon to be studied by anatomists and physiologists. These studies may lead to new discoveries concerning the composition and metabolism of our body.

I wish to speak to you of a substance which I have called lanolin, the biological importance of which I have already had occasion to mention in this country.

Lanolin is a cholesterine fat, which differs from the ordinary fat of the *pamisculus adiposus* through its containing, instead of glycerin, the brilliant crystals of cholesterine, which are so well known to every microscopist. Besides cholesterine, these fats contain other substances which are similar to cholesterine, but which have nothing in common with glycerin. In order to give you an idea of the differences which exist between these two sorts of fat, I may mention that cholesterine fats are not decomposed by boiling with alkaline solutions,—that is to say, they do not form soaps; while, on the other hand, glycerin fats are easily split into soap and glycerin when treated in the same way. The decomposition of glycerin fats into fatty acids and cholesterine, or cholesterine-like substances, can only be produced by the action of a strong solution of alkali in alcohol. We have, therefore, to deal with a very stable chemical compound.

I have found yet another difference between these two sorts of fat. Lanolin absorbs water very readily. By simply stirring together a cholesterine fat and water, more than one hundred per cent. of the latter can

be incorporated with it, and a soft yellowish mass is formed, which is the lanolin properly so called. I have named *lanolinum anhydricum* the cholesterine fat deprived of water. Neutral glycerin fats, vaseline and petroleum fat, do not absorb water, or only absorb it in very small quantity.

Lanolin can be extracted from the fat contained in the wool of sheep; this fat when unpurified is called wool oil.

It has been known for a very long time among the agricultural and cattle-breeding populations, and its old designation was *œsypus*.

I could not, without taking up too much of your time, give you the history of this *œsypus*. I shall simply tell you that *œsypus* was already used in the time of Herodotus. Dioscorides describes the preparation of *œsypus* from wool, and his description is reproduced in most of the pharmacopœias published up to the eighteenth century.

It was also used by the ancients as a cosmetic, and Ovid mentions it in his *Ars Amatoria*. The Roman ladies anointed their faces and skin with *œsypus* brought from Athens, and this in spite of its repulsive nature. Lanolin continued to be employed during the Middle Ages, as Milton has pointed out to us. He has found the *œsypus* mentioned in the Sloane edition of Hieronymus Srascatorius.\*

*œsypus* was bound to be abandoned, as the impurities which it contained, especially rancid fatty acids, often produced irritation through the skin. Many substances, called by fantastic names, have been recommended as substitutes for *œsypus*, but they all contained fatty acids, and many impure substances of this nature have been produced since my researches, and the name lanolin, which I have introduced for a definite substance, is improperly applied to them. In my opinion the best method consists in separating the lanolin from its emulsion by centrifugal action. The emulsion must be previously sterilized by the action of heat and alkalies. Distillation can, unfortunately, not be used, as it causes a partial decomposition and an increase in the quantity of fatty acids. When lanolin was first introduced by me I recommended that it should be mixed with fat; but I am pleased to be able to withdraw this opinion, as I have succeeded in removing from lanolin the sticky

\* Hieronymi Srascatorii, *Syphilis sive morbus gallieni*, Londini, 1884 (publications of the Sloane Society). Interea si membra dolor convulse malignus Torqueat *œsypo* propterea lenire dolorem mastichinoque olio.

cholesterine fats. It has thus become possible to obtain a substance which, in the state of lanolinum anhydricum and of lanolin, possesses the necessary softness. Referring to what I said in the beginning of my communication, I must now examine if lanolin is, unlike vaseline and fats, a substance similar to the fat contained in the skin and keratinous tissues.

My researches have led me to believe that it is always present wherever keratinous tissue is formed.

As to the origin of this cholesterine fat, it may be asked whether it is secreted by glands or formed simultaneously with the keratinous tissue. I can answer that the horny tissues are full of lanolin even where there are no glands to produce it. The degree of brilliancy and elasticity of the horny tissue is in direct proportion to the amount of lanolin contained in it. I must not forget to say, that some researches made by French experimenters have been of great interest to me while I was working on the subject. Berthelot\* has shown many years ago that it is possible to combine synthetically cholesterine and fatty acids. He has also foreseen that this fat might be found in nature. I have found that the researches of Hartmann have brilliantly confirmed those of Berthelot. I have, moreover, shown that lanolin is nearly always present in keratinous tissue.

On the other hand, Ranvier has discovered in the skin microscopical fatty globules, which have been called by him eleidin. We can also mention in this place the very important investigations of Waldeyer. We have here, possibly, the beginning of a series of researches which may lead ultimately to a more exact knowledge of the formation of lanolin in the cells of the skin. I say, therefore, that the constant presence of this fat in keratinous tissue, and the discovery of the substance itself, are the true therapeutical indications.

I have first of all shown that lanolin can be rubbed into the skin with great ease. When this rubbing is repeated several times the skin becomes distinctly softer. This application of lanolin to the skin has been found very useful for massage by Dr. Ewer.† It is a

great advantage that lanolin does not require to be removed with soap and water after massage. I may mention also that the easy penetration of the skin by lanolin explains the good results obtained with it in seborrhoea sicca. It stands to reason that the permeability of the skin varies in different persons; it is evident also that an epidermis already saturated by its natural lanolin cannot be impregnated with more fat as easily as a dry epidermis. Dr. Pawlowsky has therefore recommended to free the skin from its natural fat by means of ether before using the lanolin. There is no doubt that gray ointments prepared with lanolin are preferable to the ordinary ointments. This is the opinion of the well-known authority in Aix-la-Chapelle, Dr. Brandis.‡

It is certainly better to draw conclusions from a few carefully-observed cases than from statistics, which are more or less misleading in cases of this kind.

The following may prove interesting. One of my colleagues in Berlin prescribed to a patient an inunction of gray ointment made with lanolin. He observed already after two inunctions an irritation of the skin and the apparition of acne pustules. Wishing to enlarge my experience, I examined the ointment, and found no trace of lanolin in it. The chemist admitted that I was right, and said that a mistake had been made. After the disappearance of the skin eruption neutral carefully-prepared lanolin mercury ointment was used, and no return of the irritation was observed. I took special interest in a case of sycosis vulgaris, which had been wrongly diagnosed as parasitic sycosis. The patient, a young man of 19, had suffered five years from the disease, and had been treated without success not only by all the usual means, but also by a preparation of lanolin. The latter, however, was of bad quality, and a rapid improvement took place as soon as the pure substance was employed. I could mention to you many other cases in support of this view, but I think that the unirritating nature of lanolin is already generally admitted.

I wish now to make a few observations concerning the absorption of drugs through the skin. It must not be supposed that a substance applied to the skin, even in combination with lanolin, can be absorbed as quickly as through the intestine. It is also necessary to remember that a comparatively large quan-

\* "D'après diverses observations il ne paraît pas impossible que quelques-uns de ces éthers, le composé stéarique notamment, existent à l'état normale soit pathologique dans l'économie animale." Berthelot, *Chimie organique fondée sur la synthèse*, tom. i. p. 161. Paris, 1860.

† Die Anwendung des Lanolins bei der Massage.—*Deut. Med. Wochen.*, July 8, 1886, Berlin.

‡ Behandlung der Syphilis. Berlin: Hirschwald, 1886, 3d edition.

tity must be applied externally in order to produce the same general effects as a small quantity given by the mouth: the dose of mercury, for example, must be sixty times larger when used in the form of the ordinary gray ointment than when administered internally. Although lanolin mercury ointment is more readily absorbed than the ordinary one, it is quite certain that the quantity of mercury used must be much larger than what one would give internally. I must now explain shortly, why absorption through the skin is slow. The superficial layer of the skin is the stratum corneum; then comes the stratum lucidum; then the granular layer, in which lanolin is probably formed; then the deep cells of the epidermis; and at last the papilla, with one vascular loop. When fat is rubbed into the skin, it finds only this one loop through which it can be absorbed. In the intestine, on the contrary, every villus contains numerous blood-vessels; hence the great difference in the power and rapidity of absorption.

I must end with a few remarks on a point of importance concerning the use of lanolin, which shows very evidently the difference between it and ordinary fat. When lanolin is used on mucous surfaces it never forms a scab; this has been, I believe, first noticed by B. Fraenkel, of Berlin. It may be explained in the following way: lanolin has a great affinity for water, and this peculiarity explains why it adheres intimately to mucous membranes; fat and vaseline, on the contrary, remain separated from the mucous surface by their natural watery secretion.

It would lead me too far if I were to consider in detail the distribution of lanolin in the body, but I have reason to believe that it is found not only in the keratinous tissues but also in the blood, liver, and other organs; never in the *pamisculus adiposus*. Further researches will elucidate this question.

It has been objected to me that lanolin, which was known to the ancients and used for centuries, would not have been abandoned if it had been really useful. To this I answer, that what they used was *œsypus*,—that is to say, impure wool oil, which has many disadvantages and dangers. I cannot, therefore, lay too much importance on the fact that pure neutral lanolin must be used; not those substances which are sometimes falsely called lanolin, but which are in reality only impure acid wool oil, or products of distillation which contain still larger quantities of acids.

We see something analogous in the case of

opium, after it had been used in the form of electuary theriaca,—that is to say, of an impure compound of opium. It fell into discredit for a long time, partly also through prejudice, and you know that Paracelsus was the first to reintroduce it in its pure state under the name of laudanum.

Thus in lanolin I introduce to you a substance which, like many others, is old as history in its primitive forms, new as our most modern research in its derivative form. To transform the old, to apply to it the alchemy of science, to purify it, and to utilize it for the benefit of mankind, this is our aim. This has been my labor. I have the ambition and the belief to have rendered a service to humanity. A new fatty substance, neutral, miscible with water, highly absorbable by the skin, is a desideratum. Such is lanolin, which I introduce to you, and for which I predict a long career of great usefulness in the dermatological therapeutics and in the hygiene of the skin.

---

#### TEA AND ITS ALKALOID, THEINE.

By THOS. J. MAYS, M.D., PHILADELPHIA, PA.

THE tea-plant is a shrub growing from twenty to thirty feet high, and is indigenous to the southern part of Asia, but is extensively cultivated in China, Japan, and in South America, as well as to some extent in the United States. Its use as a beverage dates from a very early period in Chinese history, but the Greeks and Romans knew nothing of it, and it was only introduced into Europe about the year 1657. The botanical origin of tea is *Thea Bohea*, *T. viridis*, *T. sinensis*, and *T. assamica*, and a few hybrids; and the many varieties of tea in the market are prepared by selecting young or old leaves, and subjecting them to various processes of treatment. Thus, green tea is obtained from young leaves, which are roasted over a wood-fire for a few hours after being plucked; and black tea is made by allowing the leaves, after being gathered, to lie in heaps for ten or twelve hours, and undergo a slight fermentation, and then are slowly dried over a charcoal fire (Blyth). Hyson, Young Hyson, Gunpowder, and Imperial are the most popular kinds of green tea, and Oolong, Pekoe, and Souchong are the best-known black teas.

The chief constituents of tea are an essential oil, boheic acid, tannin, and *theine*, the last of which is the active principle of the

plant, and exists in very nearly the same proportion in both varieties of tea.

Tea was probably first used as a medicine. It is a very interesting fact that the development of most civilized countries is associated with the history of certain plants which have originally been employed in the form of hot infusions in cases of ailments, and afterwards became domestic beverages. Our own mountain tea (*Gaultheria procumbens*), and the New Jersey tea (*Canothus Americanus*), and other plants are instances of a similar kind. Then, again, poor or insipid water, or scarcity of food, may be the means of leading people to employ hot vegetable infusions for the double purpose of making their drinking fluid more palatable and healthful, and of extracting any nutriment or stimulus that may exist therein. The former object is well exemplified by the inhabitants of the northern portion of China. The river Pehio, which flows through this part of the country, is so heavily laden with vegetable and animal impurities that it emits an offensive smell. This water the Chinese never drink except in the form of tea, and then they secure entire immunity from its unhealthfulness.

It is very strange that customs which survive centuries, and which are apparently of entire insignificance, should in a latent state contain an important germ of truth. This is strikingly true of tea. Never having received a great deal of scientific investigation, it was not believed to possess much more virtue than that which it furnishes as a stimulating beverage; yet from a very remote period moist tea-leaves have been regarded as a very valuable local application by the popular mind. It is a common practice in our own day, especially in inflammation and injury of the eyes, face, etc., to apply tea-leaves for the purpose of reducing the local inflammation and the abnormal sensibility. It was after such reflections, about a year ago, when everybody, like myself, was infatuated with the idea of discovering a new local anæsthetic, that I began to investigate the physiological action of theine, and soon found that its pain-relieving power was no less remarkable when introduced beneath the skin than was that of cocaine when applied to the surface of the body. Not only was its analgesic action well demonstrated by these experiments, but the important fact was also developed that its physiological action was markedly different from that of caffeine, with which it was hitherto considered identical.

During the time and after my first experi-

ments were made, I was unaware that theine and caffeine were manufactured indiscriminately from tea, coffee, kola-nut, or Paraguay tea, and that they were sold out of the same bottle, and labelled according to the desires of the customers. Inquiry, however, soon established this fact, and a complete review of my former work became, of course, necessary. What I then used for theine was undoubtedly theine, for it so happens that it is cheaper to manufacture the alkaloid out of tea than out of coffee; hence very nearly all the theine and caffeine in the market is theine. The nature of that which I used for caffeine is more uncertain. It could not have been pure theine, for in that case I could not have obtained the varying products which I did, but it may have been theine mixed with caffeine.

In view of this unsatisfactory condition of the ordinary theine and caffeine for experimental purposes, Mr. William Harris, of Philadelphia, manufactured both alkaloids for me from tea and coffee, respectively, and quite recently I received the same alkaloids made from the same source from Merck, of Darmstadt. After investigating these preparations very thoroughly, I found that the difference in their physiological action is greater than I was led to suspect in my earlier experiments.

Theine and caffeine were investigated experimentally by Aubert, Albers, Amory, Bennett, McKendrick, Burnett, Léven, and others, and, with a single exception, they all concluded that they are identical in their action, but not one of them succeeded in finding the anæsthetic property of theine. This, I think, can only be explained on two grounds,—first, that they used the same alkaloid under different names; second, if they employed separate alkaloids, their methods of investigation were not sufficiently accurate to show the special action of each agent. Léven, who it appears experimented with the separated and genuine alkaloids in 1868, showed that theine produced convulsions in frogs, while caffeine did not; and that the lethal dose of theine was larger than that of caffeine. This is confirmed by my own inquiry. From my experiments on frogs, which will not be given here in detail, I drew the following conclusions:

They agree in the following—

1. They first affect the anterior extremities.
2. They diminish respiration.
3. They produce hyperæsthesia during the latter stage of the poisoning process.

They differ in the following—

1. Theine principally influences sensation, while caffeine does not.

2. Theine produces spontaneous spasms and convulsions, while caffeine does not.

3. Theine impairs the nasal reflex early in the poisoning process, while caffeine does not, if at all, until in the very last stage.

4. The lethal dose of theine is larger than that of caffeine.

I hope the above indicated differences will be obvious enough to convince even the most sceptical that theine and caffeine can no longer be regarded as identical, so far as their physiological action on the frog is concerned. In order to show to myself, as well as to others, that there was a decided difference between the two, and that I did not practice any unconscious self-deception, I frequently tested the contents of two numbered vials, one of which contained theine and the other caffeine, but which were only known to me by their numbers, and I never failed to designate the true nature of each specimen after testing its action on the frog. This is, indeed, a crucial experiment, and it very clearly demonstrates that the toxicological tests of experimental physiology are more accurate and delicate than those of physics and chemistry combined.

The argument which has been advanced against my deductions that the theine and caffeine employed by me were probably not chemically pure, must, I think, fall to the ground, when it is taken into consideration that precisely identical results were obtained from two separate manufactures of both alkaloids, against neither of which the charge of contamination can be brought. In the early part of my experimental review I did use preparations of both which were not altogether free from the coloring-matter of the plants, but I found the same differences as those which were brought out subsequently by the purer specimens. However, if the objection of impurity is still urged, it is incumbent on those who make it to manufacture such specimens of both alkaloids which will satisfy their ideal of purity, and have them subjected to a proper test for the purpose of finding out whether they fail to give a differential physiological reaction.

Enough evidence has now been adduced to show that theine and caffeine, while they have properties in common, also differ so widely in others that their separate manufacture becomes imperative in order that they may be more fully investigated both physiologically and clinically; and it further teaches that a knowledge of the chemical constitution of a substance is a very feeble and misleading guide to its physiological action.

The action of theine and caffeine on man in a separate state has not yet been sufficiently studied to draw any comparison between them, and it is quite obvious that, owing to the promiscuous manufacture of the two alkaloids, it is very difficult to decide whether, in the so-called cases of caffeine poisoning, the effects were due to theine or to caffeine. My own experiments on man with theine show that the subcutaneous injection of moderate doses (one-third of a grain) produce numbness of arm and hand below seat of injection; a feeling of coldness; an occasional disturbance of the temperature in the member under its influence; a slight reduction in the pulse-rate; no impairment of motion; and no intoxication of the brain. The anæsthesia was much more marked in some individuals than in others, and the temperature disturbance was irregular. Out of four cases in which the temperature was tested, it showed no difference in one, and in another one the uninjected hand was slightly higher ( $0.4^{\circ}$  Fahr.) in temperature than the injected one. In two there was quite a marked fall in temperature,—one  $0.8^{\circ}$  Fahr. and the other  $1.2^{\circ}$  Fahr. in the hand of the injected arm than in that of the uninjected one. And, strange to say, the hand which showed the greatest depression in temperature experienced the least anæsthesia.

Physiological investigation therefore demonstrates that theine possesses the power of producing anæsthesia, and clinical experience has already proven that this property is sufficiently potent to be of the most marked advantage in the treatment of painful diseases.\* In addition to the cases there detailed, I have since then treated many varied kinds of pain with the greatest satisfaction. Not only have I found it efficacious in all cases of neuralgia, but it is equally curative in many cases of pain in the extremities of rheumatic origin, lumbago, etc. It also gives unmitigated relief to the intense pains and local spasms which are met during the progress of locomotor ataxia. I have also known it to modify very markedly the pains incidental to carbuncle and to other inflammatory processes. It does not only relieve the pain, but indirectly also improves locomotive power.

The action of theine is almost entirely limited to the region below the seat of injection. There can be no doubt that after its introduction it enters the general circulation and is

\* See my article on "The Analgesic Action of Theine," in the *Medical News* for April 17, 1886.

conveyed throughout the whole body, yet, so far as my experience extends, there is not the least evidence to show that in man it affects any portion of the body above the seat of its injection unless it is given in immoderate doses. In virtue of this localized action theine possesses a marked advantage over other anodynes. Morphine, atropine, and their analogues chiefly exert their influence through a central and not through a peripheral action; hence the after-effects which so often follow the employment of the latter agents is absent in theine, and must not be left out of account in making up an estimate of the comparative value of these remedies.

The consumption of tea is enormous. Great Britain alone consumes eighty million pounds annually, and the United States about seventy million pounds in the same time. It is evident that an agent used on such a gigantic scale must either confer a benefit or an injury on the whole civilized world; hence it is of great interest to inquire into its probable effect on the human economy. Much has been written and spoken on this subject. Quite recently Dr. Bullard, of Boston, read a paper on "Chronic Tea-Poisoning"\* before the Suffolk District Medical Society, which elicited very favorable comments both from the meeting before which it was read and from the medical press, and if the conclusions reached in his paper can be fully substantiated it necessarily follows that tea is a *most insidious* poison, and should be expunged from the list of our hitherto unsuspected and innocent beverages. I think, however, that the importance of the subject demands that the data upon which the argument of the paper is founded should be exposed somewhat to the light of sober criticism before the deductions derived therefrom are ultimately accepted.

Dr. Bullard bases his statistics on an examination of one hundred and sixty-three dispensary patients who were supposed to suffer from the toxic effects of tea, and for the sake of comparison he takes as a standard the symptoms which were attributed to the poisonous action of tea by Dr. Morton, who had investigated the symptoms and conditions of five tea-tasters, and also tested the action of tea on himself as far back as 1879.† Dr. Morton concludes that the continued and immoderate

use of tea led to headache, vertigo, ringing in the ears, tremulousness, nervousness, exhaustion of mind and body, with disinclination to mental and physical exertion, increased and irregular action of the heart, dyspepsia, diminution of the amount of urine and of urea, and retardation of the metamorphosis of tissue. Now, these conclusions, we have a right to assume, are based on conditions found in persons who were most certainly exposed to the almost continuous influence of tea, and here, if anywhere, typical symptoms of tea-poisoning should be found. Therefore, with no inclination to demand a yield under the color of authority, we are entitled to ask of Dr. Bullard that when he renders judgment against an agent of almost universal consumption, it shall be done in accordance with the standard which he erects for his guide. This he evidently failed to do, for, of the most prominent symptoms laid down by Dr. Morton as being indicative of chronic tea-poisoning, less than one-half of the cases tabulated showed the least trace. Thus, of headache, only thirty per cent. suffered; of vertigo and ringing in the ears, none; of nervousness, forty-two per cent.; of exhaustion of mind and body, etc., eight per cent.; of palpitation of the heart, forty-two per cent.; of dyspepsia, fifty-two per cent.; while the most important and the most certain of all the physical signs noted by Dr. Morton, viz., the diminution of urine and of urea, are left entirely out of contemplation by Dr. Bullard. But even these figures become very seriously impeached when it is considered that one hundred and fifty-one of the one hundred and sixty-three persons examined were females; for it is a very notorious fact that the great majority of that sex, especially among dispensary patients, are liable to headache, nervousness, palpitation, dyspepsia, etc., whether they drink tea or not.

But the most serious fallacy in the paper seems to me to be the small quantity of tea which is supposed to be capable of producing such toxic symptoms. Out of sixty-eight patients complaining of tea-poisoning noted by Dr. Bullard, thirty-nine drank from two to five cups of tea a day only, and twenty-nine from five to eight a day,—an average of 4.8 cups per day. Now, if we allow one-third of a grain of theine to each cup of tea (which is certainly a very liberal allowance), the average amount of theine imbibed per day by the first series of cases was not quite one and two-thirds grains, while the latter series consumed from two to two and two-thirds grains of theine per day.

\* *Boston Med. and Surgical Journal* for April 8, 1886.

† "Toxic Effects of Tea," by Dr. W. J. Morton, in *New York Medical Record* for July 12, 1879.

These figures entirely contradict my own observations in the hypodermic use of theine. Since I became interested in a study of the physiological and clinical action of this alkaloid, I have found that one-half of a grain constitutes a moderate and an ordinary sufficient dose as an anodyne in neuralgia, but I frequently inject as much as two and one-half grains without experiencing anything except the happiest results. To one patient, who was suffering from the most intense neuralgia of both lumbo-sacral and left cervico-brachial plexuses, which was accompanied by sleeplessness, spasm of the muscles of both legs and of those of the left arm, I gave two and one-half grains of theine subcutaneously in four different localities along the spine, with instantaneous relief to the pain and the induction of sleep during the following night. This amount was injected daily for twenty-one days in succession, at the end of which time he was almost entirely free from the pain, improved in appetite and sleep, and felt better in every way. In another case of locomotor ataxia, I injected two and one-half grains of theine in different spots along the spine every other day, chiefly for the purpose of relieving the pain and contractions in the extremities, as well as the constriction around the chest. It removed all these difficulties, and made the patient feel more comfortable than before.

The transparency of the argument becomes manifest at once, when we consider that two and one-half grains hypodermically are at the very lowest calculation equivalent to ten grains given by the mouth; and if this amount can be given with perfect immunity at one time, as in the cases just cited, how can two and two-thirds grains, which was the largest amount of theine imbibed by any of Dr. Bullard's patients, produce any toxic symptoms, and that, too, when it is taken in divided doses during the course of twenty-four hours?

That tea is not such a poisonous agent as one would infer from reading Dr. Bullard's paper, is also confirmed by Dr. C. L. Dana,\* of New York, who, following the investigations of Dr. Morton, already alluded to, made similar inquiries regarding the influence of tea upon tea-tasters, and he was led to form conclusions diametrically opposed to those of Dr. Morton, and which materially vitiate the truthfulness of the standard with which Dr.

Bullard compared the symptoms of his patients. In all, Dr. Dana examined ten persons who were engaged in that pursuit, five of whom were old men, had been in the business for more than half of their lifetime, some of whom tasted from two hundred to four hundred cups of tea in a day, and in none of these cases—all of which, according to Dr. Dana's statement, imbibed about four grains of theine daily—was there the slightest evidence of tea-poisoning. The late Dr. Beard † also investigated chronic tea-poisoning, and found that his results were in complete harmony with those of Dr. Dana.

I am sorry to see room for so much fault-finding in a paper on which a great deal of time and labor has obviously been bestowed; but in the interest of fairness to an agent which is a household pet in almost every family in the land, I feel called upon to make the above adverse remarks, not in the belief, however, that tea-drinking has no poison-line, but that Dr. Bullard has far undershot it. Moreover, I trust that he will realize this, and renew the research in the near future with the same but better-directed enthusiasm that he displays in the present work.

1716 CHESTNUT STREET.

#### THE ESSENTIAL NATURE AND SCIENTIFIC THERAPEUTICS OF CHOLERA INFANTUM.

By F. C. HERR, M.D., OTTAWA, KANSAS.

"ALL science," says Emerson, "has one aim, namely, to find a theory of nature. Whenever a true theory appears it will be its own evidence. Its test is that it will explain all phenomena."

In the kaleidoscopic history of medical science it has been the fate of theories to rise and fall in rapid succession. What to-day is deemed adequate to the ends of scientific medicine, to-morrow is cast aside as inadequate to that end and worthless. This want of permanency in medical theories offers a very ready explanation of the present uncertain and chaotic state of therapeutic science. The patient labors of many investigators have extorted from nature's storehouse a multitude of facts, which, if properly interpreted and applied, might give us a comprehensive theory of medical practice. "Of what use," says Dr. John Tilt (*Change of Life*, p. 61) "is a great array of facts in medicine unless they

\* See Dr. Dana's paper in *N. Y. Med. Record*, January 24, 1880.

† "Nervous Exhaustion," by Geo. M. Beard, p. 151.

lead to a sound theory explaining their production and preventing their occurrence. Stones only cumber the ground till the architect puts them in place."

Perhaps no graver subject could enlist the attention of the physician than that which concerns the health and life of infants during the hot summer weather. The frequency and the fatality of cholera infantum, as well as the uncertainty of therapeutics in controlling its history, invest it with profound interest, and mark it as a subject requiring careful investigation. Whatever of misgiving and of ill-success may be reputed to the past in our relation with this disease, it is obvious to the writer that the present outlook threatens to revolutionize old hypotheses and old modes of practice, and yield results which will justify the declaration that "cholera infantum is *now* a manageable disease."

The present senior editor of the THERAPEUTIC GAZETTE long ago paved the way for a more enlightened practice within the scope of febrile diseases, and it seems clear to the writer that any scientific classification of disease must assign cholera infantum to the group of pyrexias. It may go a long time before this view will become the accepted doctrine with the profession, but facts are daily accumulating which fortify this opinion, and its ultimate acceptance is assured beyond the peradventure of a doubt. Tennyson has well said, "Science moves, but slowly, slowly, creeping on from point to point." Smallpox has lost its terrors through the power of prophylaxis in vaccination. Hydrophobia has been handicapped by the experimental researches of Pasteur, and one by one will these mortal foes of health come within the limit of controlling power. But we *must* break the moorings which link us to the ancient philosophy of our art. The medical practitioner who draws the inspiration of his therapeutic power from text-books will find a sad sequel to his summer's experience with cholera infantum. The recognized therapeutic resources of the past have been painfully ineffective in their application to this disease, and this inefficiency grew out of mistaken conceptions regarding the etiological and pathological basis of the disorder. The popular belief has been the professional belief in respect to the causation of cholera infantum, and the practice has been in accordance with this belief, namely, that food and dentition were the active factors in the production of cholera infantum. I own that food may be the sole excitant of morbid action in the gas-

tro-intestinal system, but food alone does not originate that morbid entity which we designate cholera infantum. Keating says (Archives of Pediatrics, May, 1885), "We have varieties of disease dependent on the character of the food, and others upon the condition of the individual;" and Trousseau declares (Clinical Medicine, vol. ii. p. 456), "Indigestion will be caused and maintained which will lead to diarrhoea, and this diarrhoea, again, under certain circumstances will become the starting-point of cholera infantum." It would be interesting to know just what circumstances Trousseau here refers to, as it is obvious he does not regard food a potential factor in the etiology of infantile cholera. Out of the importance which has been accorded this food consideration as an elementary factor in the causation of this disease has grown the doctrine that the effectual prophylaxis of cholera infantum demands a judicious, well-regulated, and proper dietary. Dr. Samuel S. Adams says (Archives of Pediatrics, May, 1885), "I am convinced that many more children would be saved during various meteorological changes if more attention were paid to alimentation as a prophylactic measure." It would be a work of supererogation to urge the importance of careful feeding in these diseases of child-life. The theme has been over-written time and again, and Dr. Adams himself says (*loc. cit.*, p. 270), "If I were content to quote the best authorities on pediatrics, I could fill the pages of the largest medical journal with the most diversified opinions of men we have learned to venerate, and in the end find that each of our authorities claimed success for his method of feeding." The tendency has always been too much in the direction of exalting into perilous prominence the dietetic factor in the production of these affections. Engrossed with this thought, other lines of thought were shut off, and progress necessarily retarded.

We have never correctly apprehended the nature of cholera infantum, either as a pathological entity or in its etiological relations. The alimentary derangements which constitute a large part of the symptom-picture of cholera infantum do not compose the essential primary disease. The initial point of the morbid process is outside the alimentary system, and the phenomena of exhausting diarrhoea and emesis are consecutive in the chain of pathogenetic action. Whatever relation food does sustain to the affection is the relation of irritation, of aggravation, rather than that of causation. In this point of view it

does not lose any of its importance, but it serves to enlarge our conception of the real rôle which it does play. Day after day, week after week, and month after month the same system of methodical feeding is practised with tender infants by tender mothers for the avowed purpose of saving the little ones from the tortures and dangers incident to careless feeding. Suddenly, without premonition, the infant is seized with violent symptoms of cholera infantum. The physician is hastily summoned. He comes, looks wise, feels the pulse, takes the temperature, and asks, "What has the child eaten?" thus implying the probable accountability of food for this sudden manifestation of disorder. The systemic disturbance is profound, and Trousseau (Clinical Medicine, vol. ii. p. 455) has well said, "The local lesions in cholera infantum are insufficient to explain the profound disturbance of the whole system." The clinical history of the affection clearly shows that, as a morbid entity, it comprises more than a mere derangement of the gastro-intestinal system. In the interpretation of the phenomena which characterize the disorder, what importance shall we attach to the profound enervation, the stupor, the sunken eye, the depressed fontanelle, and the general pallor? Are not these phenomena far more grave than the diarrhoea and the emesis? Do they not denote a measure of disorder which mere diarrhoea and vomiting do not produce, and does not a scientific, comprehensive explanation of all these phenomena refer them to the same proximate cause? We must extend our researches in the sphere of life-phenomena, study more closely the relationship between physiological and pathological processes before we can answer all the complex inquiries which the subject suggests. What Drs. John Tilt and Hanfield Jones have done for the diseases of women in their studies of the pathology of the ganglionic nervous system, it remains for some student of pathology to do for these diseases of child-life. To slightly paraphrase a sentence of Dr. Tilt's, I may say that cholera infantum should be thought of as having its *fons et origo* in the ganglionic nervous system. Dr. Goodhart affirms (Diseases of Children, p. 62) that "the sympathetic system is so involved in cholera infantum as to allow the transudation of serum from the blood-vessels into the intestines, and lead to alterations in the functions of the heart, lungs, and kidneys." This same involvement of the sympathetic system permits transudation of serum into the ventricles, and leads to alterations in the func-

tions of the brain. In the Fisk Fund Prize Essay (by C. E. Banks) for 1879 it is shown that the brain is seriously involved in cholera infantum, and that there is present usually a marked degree of peripheral vascular injection of the brain substance. Hartshorn says (Reynolds's System of Medicine), "Undoubtedly many cases of so-called chronic inflammation of the bowels, as of other parts, consists really in non-inflammatory hyperæmia or passive congestion, the result of vaso-motor paresis, and consequent relaxation and distention of the vessels without exudation, although with altered secretion and increased epithelial desquamation." As long ago as 1866, Meigs and Pepper advanced cogent reasons for regarding the pathology of cholera infantum as a primary affection of the ganglionic nervous system. It has seemed to the writer that in the diarrhoea of emotion is found a happy illustration of the *modus operandi* of the cholera infantum. "The hot bath, by paralyzing the vaso-motor and cardiac inhibitory nerves, will give rise to quickened pulse, with lower tension, frequent respiration, paracardial oppression, giddiness, faintness, and muscular languor" (Bartholow). Charles D. F. Phillips says (Materia Medica and Therapeutics, vol. i. p. 136), "Large draughts of cold water, by giving shock to the abdominal sympathetic, may cause nausea, faintness, actual syncope, and in some cases even death." These references bring to mind familiar experience, and they aptly illustrate how a variety of factors may be potential in exciting the same or identical morbid phenomena. The depression, and weakness, and pallor, and intestinal relaxation, with emesis, which sometimes come with the suddenness of surprise to infants in apparent good health, can be ascribed to no other influence than a paretic condition of the vaso-motor nervous system. Extreme, long-continued elevation of atmospheric temperature, as observed in temperate and tropical climates, supplies all the conditions necessary for the evolution of cholera infantum. The writer, who then resided in Philadelphia, has a vivid recollection of the ravages wrought by high temperature during one week in July, 1876. Five hundred deaths occurred in this week in infants under two years of age. The total mortality from all causes and at all ages often does not exceed three hundred per week. It remains an undetermined question just how far meteorological changes are responsible for these disorders. Dr. James Frederick Goodhart, in discussing the influence which barometric

changes have upon summer diarrhoea, says, "What such reactions may indicate etiologically; how far, that is to say, such conditions indicate changes in the food, and how far act immediately upon the system, it is impossible to say, and, happily for the purposes of therapeutics, though the facts are worthy of recognition, the treatment is unaffected."

This brings me to the consideration of the therapeutics of cholera infantum. If I only had to speak of Dover's powder and chalk mixture, bismuth and ipecac., and mercury with chalk, etc., I should refrain from saying anything in the belief that these matters have been fully written upon by numerous authors. Nor do I propose to discuss at length that large class of agents which have met with favor in the profession by reason of their energetic astringency, or by virtue of their influence over peristaltic action. Except in rare cases, I regard these remedies as contraindicated in the treatment of cholera infantum. Their employment has yielded no results which justify definite conclusions, and in the hands of one therapist simple chalk mixture is the available remedy, while with another the whole range of astringents from bismuth to tannic acid and the salts of lead, are brought into requisition. The evident purpose of all these agents is to modify intestinal peristalsis, and control serous effusion by counteracting the relaxation which is present. To accomplish this end does not meet the purposes of successful therapeutics. In simple entero-colitis, from local irritation, it may be quite sufficient to administer bismuth, or opium, or bicarbonate of sodium with rhubarb, or a solution of morphine with aromatic sulphuric acid, or mercury and chalk with ipecacuanha, and perhaps in some cases strong solutions of nitrate of silver, as suggested by Trousseau. But in the therapeutics of cholera infantum it will be found that these remedies do not meet the pathological indications. They may control the excessive discharges, but they will not correct the disordered nervous system, which is the underlying causal factor in the disease.

It will be found from a careful study of the subject in its entirety that those medicines are most available which, from a study of their physiological action, are found to influence the ganglionic nervous system in the direction of stimulation. If the theoretic consideration of vaso-motor paresis is the essential pathological condition of this disease, then it follows that the indications for treatment are met in the employment of agents which an-

tagonize this morbid state. I may mention in this class of agents the following ones as the more important: aconite, belladonna, arsenic, nux vomica, opium, hydrocyanic acid, caffeine, and cocaine. I am well aware that the employment of these remedies in the treatment of cholera infantum is not the established practice, but it will not for that reason be contended by any one that they are without efficiency. It is obvious that without a clear apprehension of the pathological nature of any disease its therapeutics must be a matter of pure speculation. But here we have an hypothesis which explains all the phenomena of this disorder, and upon it may be builded a practice which will yield the results which science long has sought.

Dr. W. Byford Ryan (*American Practitioner*, May, 1885) says, "The indications for treatment in cholera infantum are, first, to relieve visceral engorgement; second, to maintain capillary action of the entire economy; third, to give tone to the muscular and mucous coats of the bowels; and fourth, to supply proper nutriment." These indications Dr. Ryan believes are largely met by the administration of belladonna, and in my own experience it has yielded excellent results. Belladonna is indicated here by reason of its action antagonizing that morbid process which is expressed in cases of cholera infantum. The diseased action and the therapeutic force of the drug are opposed to each other. The arterial depression, the vascular engorgement, the serous effusion, and great prostration all arise from paresis of the vaso-motor system, and whatever will restore the functions of this system will cure the disease. Dr. Horatio C. Wood says (*THERAPEUTIC GAZETTE*, July 15, 1885), "It is notorious that in our northern cities the infant mortality rises most extraordinarily and most abruptly upon the occurrence of a very hot spell of weather, such mortality being due to the so-called entero-colitis, the symptoms of which may be summed up as high fever, dry tongue and mouth, rapid pulse and respiration, intense thirst and vomiting, purging of greenish watery fecal or serous matters with undigested particles of food, and more or less apparent evidences of cerebral disturbance, such as insomnia, headache, contracted pupils, delirium, and finally coma. In some of these cases the bodily temperature rises to a point almost reaching the maximum attained in the sunstroke of adults, and we well remember how we used to be taught to explain to the mothers under these circumstances that the disease had gone to the child's head

and was hopeless. They are in reality forms of thermic fever, the intestinal condition being no more a primary condition than is the coma of adult sunstroke a primary condition ; if this fact were clearly recognized by our practitioners of medicine the mortality rate in our large cities among children in hot spells would be enormously reduced." "These cases," he continues, "are to be relieved not by calomel or astringents, or any other drug which relieves inflammation of the intestines, but by external use of cold water." Dr. Wood has been a strong advocate of this practice, and I have no doubt he has saved lives where without it death would have supervened. But we have spoken only of belladonna. Aconite holds a rank in no degree inferior to belladonna. In the first stages of cholera infantum it is especially valuable. When the pyrexia is high, the evacuations frequent, and the distress very marked, aconite will afford very prompt and effectual relief. Great caution is essential that too much is not given, else its therapeutic power will be lost in its toxic action. At first sight it may appear a gratuitous assumption to many that aconite should exercise any influence over this disease ; but when it is remembered that aconite has a decided influence over the vaso-motor system, producing free diaphoresis, and stimulating the cardiac inhibitory nerves, it is obvious that it meets the indications for treatment. Hydrocyanic acid, by reason of its stimulating action upon the vaso-motor centres, is also valuable in these cases of undoubted paresis of the sympathetic. Dr. W. M. Ewing, of this city, informs me that he derives excellent results from the administration of ergotine in these forms of disorder, and in the limited number of cases in which I have tried it the result has not been disappointing. From its well-known physiological action, it would be indicated in these disorders.

I come now to speak of a remedy which I believe to be new in the treatment of cholera infantum, and one, too, which, from clinical experience, I feel assured will take a high rank as a potent agent for the relief and cure of this distressing affection. I apprehend the average reader will regard this a purely novel rather than a really practical suggestion, but I have no hesitation in saying that with me cocaine has established its claim to a place by the side of any remedy which the therapist may have recourse to. I was induced to try this remedy more than a year and a half ago in the case of my own child. The symptoms which characterized the case were profuse in-

testinal evacuations and vomiting, with great weakness, pallor of the skin, sinking of the eyes, coolness of the cheeks, hands, and feet, increasing frequency of pulse, and slight cyanosis of the face. I administered the sixth of a grain of the salt of the hydrochlorate every two hours with the best conceivable results. Since then I have frequently employed it with equally good results in similar cases. Perhaps I am unreasonably wedded to the remedy, but when I say that during two summers of long-continued extreme temperature I have not failed to cure every case of cholera infantum, I have reason for confidence. Grave a disease as is cholera infantum, its great mortality has been possible only because science had not indicated its rational, scientific treatment. We have in cocaine an agent which meets a double indication ; it is a stimulant to the ganglionic centres, and at the same time a sedative to the sensitive gastro-intestinal mucous membrane.

In the THERAPEUTIC GAZETTE for July, 1886, Dr. J. H. Musser says, "A very successful run of cases of cholera infantum treated by the very frequent use of Dover's powder and calomel in small doses, dry on the tongue, has made the writer rely chiefly on these drugs." Who has not tried Dover's powder and calomel in small doses dry on the tongue? Who feels that when *this is done* the resources of science are exhausted? It is because this practice is disappointing and unsuccessful that the writer has abandoned it for a practice founded upon science, and as far removed from empiricism as medical practice can be. Dr. John Tilt says, "Vital acts are never found cut and squared with mathematical precision," but the medicine of the future must diligently seek to eliminate every element of uncertainty, and we will have established an art whose foundation rests upon a science as comprehensive as nature.

---

#### HYOSCINE HYDROBROMATE AS A HYPNOTIC IN PRIVATE PRACTICE.

---

BY FRANCIS L. AND JOHN R. HAYNES, M.D.,  
PHILADELPHIA, PA.

"Facts, sir, facts!"—GADGRIND.

---

THIS paper is based on the administration of 338 doses of hyoscine to fifty-seven persons.

In some instances little or no effect was noticed after hyoscine, but generally one or more of the following symptoms occurred :

1. Delirium, rambling or muttering, with hallucinations of vision, resulting in attempts to grasp imaginary objects. Otherwise, it was not attended by marked muscular movement, the patient being generally contented to lie in bed.

2. Sleep, sometimes apparently natural, sometimes disturbed.

3. Intense reddening of whole face, with sensations of heat affecting the entire body.

It was not determined whether the temperature was actually elevated in such cases. Following the analogy of belladonna-poisoning, where we have noted a temperature as high as  $103^{\circ}$ , it seems probable that hyoscine-poisoning of this type is also associated with fever. But belladonna-poisoning is associated with dryness of the skin, while hyoscine does not check perspiration, though we have not noticed that it increases the activity of the sweat-glands.

Pallor of the face was seen much more frequently than flushing.

4. Muscular weakness, sometimes extreme.

5. Headache, sometimes affecting the entire cranium, sometimes frontal, and sometimes confined to region of inter-parietal suture.

6. Dryness of the throat and mouth.

7. Dilatation of pupil, with blurred vision.

The most remarkable variation was noted in the symptoms in different individuals, and, sometimes, in the same individual. This variation was but little influenced by the size of the dose. Thus we administered, personally, on the same day, under very similar circumstances, equal doses to two women (Cases 14 and 28): one was poisoned, the other fell into a pleasant sleep. In Case 26, gr.  $\frac{1}{100}$  was followed by sleep, while gr.  $\frac{1}{8}$  produced delirium; in Case 17, gr.  $\frac{1}{100}$  produced delirium, and gr.  $\frac{1}{8}$  was followed by sleep.

We have divided our cases, roughly, into the following classes:

1. Hyoscine produced sleep, fifteen cases.
2. It produced delirium, thirteen cases.
3. It was without marked effect, or was followed by various symptoms, twenty-nine cases.

As the result of our experience, we feel constrained to state that we consider hyoscine extremely unreliable as a hypnotic, and that it should not be used in general practice, except in cases in which other hypnotics have failed.

In the few instances where the alkaloid was used for other purposes, the results were not decisive. In one case of asthma (29) it did good; in another (52) it aggravated the patient's sufferings. Used to overcome the untoward effects of morphine in one case (10) it acted charmingly; in another (42) the results first noted were nullified by subsequent

experience; and in a third (11) the combined bad effects of both drugs were shown.

Merck's hyoscine was used, except in a few instances, when that of M. L. C. Marquart was given (Cases 13, 15, 16, 46, 47, 54, 55, 56, and 57). Generally we administered the drug personally, and, in all cases, the greatest care was taken both in dosage and in the report of the effects. During cool weather, a solution containing ten per cent. of alcohol was well preserved; but, in summer, in order to prevent confervoid growths, the alkaloid was dissolved in pure alcohol (gr.  $\frac{1}{100}$  to  $\frac{1}{xx}$ ).

#### I. HYOSCINE PRODUCED SLEEP.

1. Female, aged 19, marked insomnia from profound anaemia.

Hyoscine, gr.  $\frac{1}{100}$ , at bedtime gave seven hours' refreshing sleep. This was repeated sixteen times, at intervals, with similar effects, to the great benefit of the patient.

2. Female, aged 19, last stage of phthisis.

Hyoscine, gr.  $\frac{1}{100}$ , in daytime, produced sleep for one and one-half hours; gr.  $\frac{1}{80}$ , three and one-half hours. Repeated twelve times, with similar effects.

3. Female, aged 60, insomnia from old age, bronchitis.

Hyoscine, gr.  $\frac{1}{100}$ , at 7 P.M. Fell asleep at 7.30, and slept most of night; gr.  $\frac{1}{80}$ , next day, produced sleep for an hour. Repeated ten times, with similar results. She thought the drug relieved her cough.

4. Male, aged 45, gastric catarrh and severe headache, produced by drink.

Hyoscine, gr.  $\frac{1}{80}$ , at 7.30 P.M. Fell asleep at twelve, and awoke at six; well.

5. Male, aged 52, delirium from drink; almost sleepless for a week; hallucinations of vision, hiccough, vomiting.

*First night.*—Hyoscine, gr.  $\frac{1}{8}$ , in divided doses, was given between 3 P.M. and 12 M. next day. During this time, he slept two hours, or about as long as during the previous night. Stomach was settled, and his general condition was greatly improved, as the result of abstinence.

*Second night.*—Hyoscine, gr.  $\frac{1}{8}$ , in four doses. Slept six and one-half hours, and awoke free from hiccough.

*Third night.*—Slept about one-half as long as second night, without hyoscine.

*Fourth night.*—Hyoscine, gr.  $\frac{1}{80}$ . Slept eight hours.

6. Female, aged 35, confined to bed by miscarriage.

Hyoscine, gr.  $\frac{1}{80}$ , at 10 A.M. Drowsy all day; slept an hour in the afternoon.

7. Female, insomnia, acute pneumonia.

Hyoscine, gr.  $\frac{1}{80}$ , at 8 P.M. Fell asleep in fifteen minutes, and slept six hours.

8. Female, aged 35, pharyngitis, causing fever, severe headache, and sleeplessness.

Morph., gr. ii, in three doses, by suppository, given during the night, failed to produce sleep or any amelioration of suffering. Hyoscine, gr.  $\frac{1}{8}$ , in four doses during next day. Slept very well during most of day and succeeding night.

*On second day.*—Took gr.  $\frac{1}{8}$ . Fell asleep in an hour, and slept an hour.

9. Female, aged 25, debility after cholera morbus.

Hyoscine, gr.  $\frac{1}{100}$ , in eight doses, during day. Slept almost continuously after first dose.

10. Female, aged 55, intestinal colic. In morning she took morphine, relieving pain, but causing (as it always does in her case) severe nausea, vomiting, and insomnia.

To relieve these symptoms, ordered at 9 P.M. hyoscine, gr.  $\frac{1}{100}$ , in two doses. Immediate relief; slept all night; well in morning. (Compare with Case 11.)

11. Female, aged 25, bronchitis.

Hyoscine, gr.  $\frac{1}{10}$ , with morph., gr. i, in ten doses, in twenty-four hours. Dozed, but did not sleep; severe nausea; hallucinations of vision.

12. Male, aged 17, convalescing from typhoid.

Hyoscine was given at intervals of several days, always in the morning. After gr.  $\frac{1}{100}$ , did not sleep as much as usual. After gr.  $\frac{1}{10}$ , slept three hours more than usual. After gr.  $\frac{1}{5}$ , did not sleep. After gr.  $\frac{1}{10}$  on three occasions, and gr.  $\frac{1}{5}$  on one occasion, he slept one and a half hours more than usual. Hyoscine did not modify the profuse sweating, which was one of this patient's symptoms. Twice flushing of the face and dilatation of pupils occurred, once headache, but never any throat dryness.

13. Female, aged 25, insomnia following intermittent.

*First and second nights.*—Did not sleep.

*Third night.*—Hyoscine, gr.  $\frac{1}{100}$ , was given at 8 P.M., when she felt no inclination to sleep. Fell asleep at 8.30, and awoke at twelve. At 12.30 received hyoscine, gr.  $\frac{1}{100}$ . Fell asleep at one and awoke at five.

*Fourth night.*—Hyoscine, gr.  $\frac{1}{100}$ , at nine o'clock. Fell asleep at ten and awoke at six next morning.

14. Female, aged 40, eighth day puerperium.

Hyoscine, gr.  $\frac{1}{100}$ , at 1 P.M. The only effect was a pleasant sleep, commencing in fifteen minutes and lasting for three hours, when she was awakened by callers. (Refer to Case 28.)

15. Female, aged 28, phthisis, had recently recovered from severe whiskey-gastritis. Had not had good night's rest for two weeks.

Hyoscine, gr.  $\frac{1}{100}$ , at 10.30 P.M. Fell asleep at eleven, awoke at three for a few minutes; then slept till five. Vomited. Fell asleep again at 5.30 A.M., and slept until eleven. Felt wretched and vomited freely all day. Refused any more of "that poison."

16. Female, aged 20, insomnia, typhoid.

Hyoscine, gr.  $\frac{1}{10}$ , in two doses at night, was followed by about three hours' sleep. No ill effects. Had not rested so well for several nights.

## II. HYOSCINE CAUSES DELIRIUM.

17. Female, aged 15, acute catarrhal pneumonia; insomnia produced by cough and fever; mind clear.

*First night.*—Hyoscine, gr.  $\frac{1}{100}$ , repeated in three hours. Slight delirium all night.

*Second night.*—Hyoscine, gr.  $\frac{1}{100}$ , at nine; delirium for four hours; then slept until morning.

*Third night.*—Hyoscine, gr.  $\frac{1}{100}$ , with same effect.

*Fourth night.*—Hyoscine, gr.  $\frac{1}{10}$ , at eight. Slept from 11 P.M. to 1 A.M. From one to two remained awake, drinking constantly, then fell asleep, and awoke at 5 A.M. No delirium from this dose.

*Fifth night.*—Hyoscine, gr.  $\frac{1}{10}$ , combined with morph.,

gr.  $\frac{1}{10}$ , at seven. Fell asleep immediately, and slept till 5 A.M.

*Sixth night.*—Slept fairly well, without hypnotic.

18. Boy, aged 9, restlessness due to gastric catarrh.

Hyoscine, gr.  $\frac{1}{10}$ , in five doses, in six hours. No sleep. After second dose, he began to talk incessantly and irrationally, and to clutch at imaginary objects; he was excited in manner. When placed on his feet, he attempted to walk, but staggered, and would have fallen, if he had not been supported. Redness of face, and dilatation of pupils. Symptoms resembled mild belladonna-poisoning, such as we have frequently seen in children, treated for whooping-cough, by large doses of that drug.

Paregoric,  $\mathfrak{zvi}$ , was given in divided doses, but he remained delirious and sleepless for seventeen hours.

19. Male, aged 40, last stage acute tuberculosis.

Hyoscine, gr.  $\frac{1}{100}$ , every eight hours, until gr.  $\frac{1}{10}$  was used; produced no sleep, but very mild, rambling delirium. Then same dose was repeated every two hours, until  $\frac{1}{100}$  additional was used. The delirium became more marked, and lasted until eight hours after the last dose, but did not seem unpleasant either to patient or nurse. Morph., gr.  $\frac{1}{2}$ , had no effect on the delirium.

The same patient took from gr.  $\frac{1}{4}$  to  $\frac{1}{2}$  of morph. every night for four nights, with the effect of producing pleasant sleep, lasting all night.

20. Female, aged 65, habitual insomnia of old age. Laudanum in large doses produced pleasant sleep; its use had become habitual at one time, but two months before taking hyoscine she had discontinued it.

Hyoscine, gr.  $\frac{1}{10}$ , in sixteen doses, in two nights, produced no sleep, but mild delirium. On the *third night* slept somewhat without hypnotic.

21. Male, aged 66, cerebral paralysis, insomnia, delirium.

Hyoscine, gr.  $\frac{1}{10}$ , in four doses, in two nights, had no effect except to make him more delirious.

Morph., gr.  $\frac{1}{2}$ , with hyoscine, gr.  $\frac{1}{10}$ , in two doses, made him sleep well, and repetition of such doses served a good purpose until his death.

22. Female, aged 60, bronchitis, insomnia.

Hyoscine, gr.  $\frac{1}{100}$ , in two doses. No sleep. Delirious all night.

Chloral, gr. xl, in two doses, was given the succeeding night, and, after five hours, produced profound sleep lasting eight hours.

23. Male, insomnia, chronic bronchitis.

Hyoscine, gr.  $\frac{1}{10}$ , at night, in two doses. No sleep. Slight delirium.

The chloral-bromide-morphine mixture, in moderate doses, produced sleep.

24. Male, acute pneumonia, sleeplessness.

Hyoscine, gr.  $\frac{1}{100}$ , in seven doses, in twenty-four hours. After first dose he became delirious (hallucinations of vision, rambling talk, kicking and pulling at bedclothes and imaginary objects), and remained so for thirty-six hours. At the twenty-fourth hour, he was ordered morph., gr.  $\frac{1}{2}$ , and in eight hours (after taking gr. i) fell asleep.

After this morphine, in moderate doses, acted well as a hypnotic.

25. Male, aged 7, cerebro-spinal meningitis (headache, fever, violent delirium, jactitation, absolute sleeplessness, opisthotonos, dilated pupils).

Hyoscine, gr.  $\frac{1}{100}$ , every three hours, until  $\frac{1}{2}$  was taken. Then  $\frac{1}{100}$ , every three hours, till  $\frac{1}{10}$  was taken. No change, except that delirium seemed more marked. Then paregoric,  $\mathfrak{zss}$ , every two hours, until  $\mathfrak{zj}$  was taken. No improvement.

Then moderate doses of chloral, bromide, and morph. produced sleep, and this mixture was used with great satisfaction, for this purpose, until he recovered (about ten days).

26. Female, aged 30, insomnia, acute rheumatism.

After hyoscine, gr.  $\frac{1}{100}$ , at 8 P.M., slept two and a quarter hours.

Two days after took gr.  $\frac{1}{100}$  at 8 A.M., and slept one hour. Three days after, gr.  $\frac{1}{8}$ , at 9.25 P.M., produced slight delirium, lasting all night. Three days after, gr.  $\frac{1}{8}$  at 11.30 P.M. Delirium until 3 A.M., then sleep until 5 A.M.

27. Female, aged 25, insomnia, due to nervousness and anæmia.

Hyoscine, gr.  $\frac{1}{8}$ , in divided doses, every night for three nights. During this time she did not sleep, but talked constantly, not allowing her room-mate to sleep. I could not determine that she was irrational. She felt so bright after taking each dose that she accused me of giving her a stimulant.

28. Female, aged 30, eighth day of puerperium.

Hyoscine, gr.  $\frac{1}{100}$ , at 1 P.M. In half an hour, dimness of vision, headache, intense burning sensation of skin, extreme sense of weakness. Then constant, unintelligible muttering. Symptoms had nearly passed away by 6 P.M., and at ten she fell asleep.

29. Female, aged 58, asthma and bronchitis, insomnia.

Hyoscine, gr.  $\frac{1}{8}$ , at 11 A.M. Slept four and a half hours; then mild delirium for eight hours. Cough and dyspnoea much improved. As she had failed to procure any relief from her previous treatment (pot. iod., with small and frequently-repeated doses of morphine), she was now directed to take hyoscine, gr.  $\frac{1}{100}$ , every two or three hours. This was so effectual that she was discharged in four days.

### III. HYOSCINE PRODUCED NEITHER SLEEP NOR DELIRIUM; BUT EITHER HAD NO EFFECT, OR WAS FOLLOWED BY VARIOUS SYMPTOMS.

30. Female, aged 24, insomnia, neurasthenia.

Hyoscine, gr.  $\frac{1}{100}$ , every night for three nights; then gr.  $\frac{1}{100}$  every night for three nights. Sleep more restless than usual; slept better after drug was discontinued. The eyesight was much impaired.

31. Female, aged 40, sleeplessness from bronchitis.

Hyoscine, gr.  $\frac{1}{100}$ , every night for eight nights caused restlessness. Slept much better without it.

Morphine in decided doses produced sleep.

32. Male, aged 48.

Hyoscine, gr.  $\frac{1}{100}$ , at 6 P.M. Remained awake and restless all night.

33. Male, aged 20, insomnia, delirium, typhoid fever.

Hyoscine, gr.  $\frac{1}{8}$ , had no effect whatever.

Morphine, in decided doses, produced sleep.

34. Male, aged 35, insomnia from excessive mental exertion.

Hyoscine, gr.  $\frac{1}{100}$ , at night, no effect; gr.  $\frac{1}{8}$ , at night,

was followed by sleep after one and a half hours, but he was disturbed by dryness of the mouth and throat, and considered that he rested much better without it.

Pot. brom.,  $\mathfrak{zij}$ , generally gave this patient a good night's rest, while chloral,  $\mathfrak{zss}$ , produced ten hours of profound sleep.

35. Female, aged 35, perimetritis.

Hyoscine, gr.  $\frac{1}{100}$ , at 10 A.M. No effect.

36. Female, aged 50, dacrocystitis.

Hyoscine, gr.  $\frac{1}{100}$ , at 10 A.M. No effect.

*Second day.*—Hyoscine, gr.  $\frac{1}{8}$ , at 12 M. For three hours felt dizzy and "drunk;" was very talkative; throat extremely dry; eyesight very dim. She was forced to lie down through great muscular weakness, but did not sleep for thirty hours.

*Eighth day.*—Hyoscine, gr.  $\frac{1}{8}$ , at 3 P.M. Effects the same, except that she slept after eight hours.

37. Adult, insomnia, typhoid fever.

Hyoscine, gr.  $\frac{1}{8}$ , at night for two nights. No effect.

38. Adult, insomnia, typhoid fever.

Hyoscine, gr.  $\frac{1}{100}$ , at night. No effect.

39. Adult, insomnia, delirium tremens.

Hyoscine, gr.  $\frac{1}{100}$ , at night. No effect.

40. Adult, insomnia.

Hyoscine, gr.  $\frac{1}{100}$ , at night. No effect.

41. Female, aged 30, puerpera.

Hyoscine, gr.  $\frac{1}{100}$ , at 11 A.M. No effect except to flush face.

Next day gr.  $\frac{1}{8}$  at 10 A.M. She did not think that she slept any more than usual.

42. Female, constant pain from sarcoma uteri.

Hyoscine, gr.  $\frac{1}{100}$ , was taken at sixteen different times day and night. She said, "It made me helpless; I could not speak or sleep, and felt as if I were sinking all the time."

Morphine stupefies this patient; causes her to doze but not to sleep, and produces cramp-like pains in the stomach and vomiting.

Morph., gr.  $\frac{1}{4}$ , with hyoscine, gr.  $\frac{1}{100}$ , produces the same effect as morphine alone, *except that no cramp or vomiting occurs.*

After the above experiments morphine alone was used daily to relieve pain, and it became evident that toleration had become established. No stomach symptoms were now felt, nor was the sensation of helplessness as great as when hyoscine also was used.

43. Female, aged 36, healthy.

Hyoscine, gr.  $\frac{1}{100}$ , at 3 P.M. had a somewhat exhilarating effect.

*After ten days*, gr.  $\frac{1}{8}$  was given at 7 A.M. Headache, marked muscular weakness, no sleep, but slight drowsiness.

*After ten days*, last experiment repeated with same result. The body temperature was taken every hour; it remained normal.

44. Female, aged 25, hydrosalpinx.

Hyoscine, gr.  $\frac{1}{8}$ , was given on two occasions during daytime. Did not sleep during day, and not as well as usual on succeeding night; weakness, etc.

45. Male, aged 63, wild delirium from acute nephritis.

Hyoscine, gr.  $\frac{1}{100}$ , was given at six different times.

Twice it was succeeded by a few hours' sleep. Four times it was without effect.

46. Male, aged 71, wild delirium, fracture neck of femur.

*First night.*—No sleep, although chloral,  $\mathfrak{D}$ ii, was given in two doses.

*Second night.*—Hyoscine, gr.  $\frac{1}{100}$ , was followed by eight hours' interrupted sleep.

*Third night.*—Hyoscine, gr.  $\frac{1}{100}$ . Wild delirium all night.

Next morning at 11.30 hyoscine, gr.  $\frac{1}{100}$ ; fell asleep at twelve and awoke very delirious at one.

After this chloral-bromide-morphine mixture, in large doses, produced sleep whenever a hypnotic was required.

47. Female, aged 18, insomnia from excessive study.

Hyoscine, gr.  $\frac{1}{100}$ , at 10.30. Fell asleep at twelve. "Frightened" sleep during remainder of night; awoke with severe headache, and declared emphatically that she "would take no more of that stuff."

48. Male, aged 14, healthy.

Hyoscine, gr.  $\frac{1}{100}$ , at 2 P.M. He was carefully watched by one of the writers, but no effect whatever was noticed.

One month after, he received gr.  $\frac{1}{100}$  at 1 P.M., and in five hours gr.  $\frac{1}{100}$ . No effect.

49. Female, aged 35, dyspepsia.

Hyoscine, gr.  $\frac{1}{80}$ , at 2 P.M. Severe headache and throat-dryness, with general malaise. Fell asleep at 10 P.M.

50. Female, aged 17.

Immediately after removal of tonsil received hyoscine, gr.  $\frac{1}{100}$ , at 2.30 P.M. In twenty minutes face became very red, and she felt very sleepy and miserable. At 10 P.M. fell asleep, but sleep was much disturbed throughout night.

51. Female, aged 22, third day puerperium.

Hyoscine, gr.  $\frac{1}{80}$ , at 11 A.M. Severe headache, redness of face, "burning" feelings, throat-dryness, thirst. Fell asleep twice, but was awakened in a few minutes by terrible dreams. Sweated profusely, as the temperature of the room was 98°.

52. Male, aged 29, mild asthma, troublesome cough, whistling rales.

*July 30*, 9 A.M.—Hyoscine, gr.  $\frac{1}{100}$ , every two hours. 7 P.M., has taken four doses; mouth and throat feel dry.

*July 31*, 9 A.M.—Slept but three-quarters of an hour last night, principally on account of dryness of throat. 7 P.M., slept about one and a half hours during day; slight frontal headache; pupils dilated; vision very indistinct.

*August 1*, 2 P.M.—The last dose was taken at 10 A.M., making gr.  $\frac{1}{50}$  in forty-eight hours. Slept three and three-quarters hours last night, making six hours in all since he commenced taking hyoscine. Now has very severe headache and extreme muscular weakness, besides symptoms mentioned above. The hyoscine symptoms passed away in about thirty-six hours more.

Although he complained constantly of throat-dryness, yet, on repeated examination, the mouth and pharynx presented a natural appearance.

53. Male, aged 25, indigestion.

Hyoscine, gr.  $\frac{1}{80}$ , at 2 P.M. Felt very drowsy, and went to bed, but could not sleep till 1 A.M. Headache, weakness, fever, redness of face, dilatation of pupils.

Hyoscine, gr.  $\frac{1}{80}$ , three days after, at 9 A.M. Staggering gait, but *no headache or dryness of throat*; anorexia. Symptoms had about disappeared by 4 P.M. (when he walked a mile), except dilatation of pupils, which was quite noticeable at the end of forty-eight hours. Fell into a sound sleep at 10 P.M.

54, 55, 56, and 57, adults, suffering from insomnia. Each received gr.  $\frac{1}{100}$  at night, without effect. Refer also to Case 11.

1924 E. CUMBERLAND STREET.

#### NOTE ON HYDROBROMATE OF HYOSCINE.

By P. S. ROOT, M.D., MONROE, MICH.

THUS far in the therapeutic literature of the uses of hyoscine I have seen mentioned no untoward effects from the use of this drug in ordinary doses (such as recommended by alienists), ranging from  $\frac{1}{100}$  to  $\frac{1}{10}$  of a grain, administered hypodermically.

The following case illustrates the fact that even smaller doses than those indicated may occasion dangerous symptoms:

Mrs. —, age 58, of full habit, the subject of "continued fever," had for a number of days suffered from persistent insomnia, not alleviated by ordinary remedies, temperature ranging from 101° to 103°; pulse, 116 to 120 and weak; further, the symptoms indicated marked functional derangement of the sympathetic nervous system. The insomnia proving intractable, and rest being a requisite, Dr. E. L. Shurly was called in consultation, and upon his recommendation, concurred in by myself, I administered  $\frac{1}{80}$  of a grain of hyoscine *per os* at 11.30 A.M. At 12.30 P.M. I was hastily summoned, and found the following condition: Patient in deep stupor, from which she could not be roused; respiration extremely shallow and 50 per minute; pulse 96, full and strong; tongue and mouth dry; pupils widely dilated; countenance suffused and livid; convulsive movement of lower extremities, etc. Suitable stimulants were administered, the patient being only able to swallow after the fluids had reached the lower pharyngeal muscles; in fine, there was no power to swallow. This condition persisted for two hours, when she could be partially roused, after which she passed into a more tranquil slumber, sleeping for a number of hours, all effects of the drug passing off, but with mitigation of many of the nervous symptoms.

After this, on a partial recurrence of the symptoms, I administered  $\frac{1}{100}$  of a grain, which was followed by the dreamful sleep characteristic of the drug. The above case

is mentioned that the profession may not be too incautious in the administration of this powerful alkaloid. I may say that investigations were made as to the possibility of mistake in dispensing, but none was found to exist; and that I administered the same dose, hypodermically, to a case of acute mania, but without even getting the characteristic effect of the drug. In conversation with my friend, Dr. Geo. P. Andrews, of Detroit, he narrated to me a case in his own practice where similar symptoms resulted from the administration of  $\frac{1}{100}$  of a grain. Finally, that hyoscine is a hypnotic of undoubted value is undeniable, but the promiscuous administration of it is not to be recommended, save with the utmost caution. From my experience, I would say that the usual dose should not be greater than  $\frac{1}{100}$  of a grain, save in cases of acute mania.

*THE USE OF AN ABDOMINAL BANDAGE  
IN THE SECOND STAGE OF LABOR,  
WITH A REPORT OF TEN  
CASES.*

BY J. WESLEY WELKER, M.D., STROMSBURG, NEB.

UP to the commencement of the second stage of labor the uterus alone is concerned in dilating the neck, but it then seems to call in aid the contraction of the abdominal muscles, and consequently both the pain and the bearing down are carried to a much higher degree. The pains are stronger, yet nevertheless the woman assists them by voluntarily contracting the abdominal muscles; and as the pains grow stronger and labor seems to be tedious, then the woman will often call on her physician for help. I believe that this assistance can be rendered by the use of an abdominal bandage, and that by it, in the second stage of labor, we may not only lessen the suffering of our patient, but at the same time shorten the duration of labor. Consequently I use the abdominal bandage for a twofold purpose: First, to lessen the suffering of my patient. To accomplish this I apply it at or before the commencement of the second stage of labor, making it just tight enough to be comfortable to my patient. Second, to shorten the duration of labor. To accomplish this end I tighten the bandage when the abdominal muscles are called upon to assist the uterus in expelling its contents. In my first cases I used simply an ordinary linen towel, which I

put around the abdomen of the woman and secured with pins, which I unpinned and tightened as the case demanded. I now use a bandage which I constructed for that purpose, which resembles in shape the lower half of a corset, except I have it open on the side, making a back and abdominal piece, which I unite by means of straps and buckles. Having it open on both sides I can adjust it more easily to fit different-sized patients. The following cases illustrate some of my results:

CASE I.—Primipara, had been in labor for thirty-six hours, os rigid, and not dilated larger than a silver dollar, and membranes protruding. I applied the abdominal bandage and ruptured the membranes, and the child was delivered in about thirty minutes. The placenta came away in about fifteen minutes.

CASE II.—Primipara, had been in labor when I arrived about twelve hours, and the membranes had been ruptured for about two hours. I at once applied my abdominal bandage, and labor was completed in twenty minutes.

CASE III.—Multipara, mother of three children. In a violent pain, just as I entered the room, the membranes were ruptured. I at once applied my abdominal bandage, and labor was complete in fifteen minutes.

CASE IV.—Primipara, had been in labor about two hours when I arrived; membranes were ruptured. I applied my bandage, and labor was complete in twenty minutes.

CASE V.—Had been in labor for six hours; membranes ruptured about fifteen minutes before I arrived. I at once applied my bandage, and labor was completed in fifteen minutes.

CASE VI.—Primipara, had been in labor for ten hours, and membranes ruptured about two hours before I arrived. I at once applied my abdominal bandage, and labor was completed in eighteen minutes.

CASE VII.—Multipara, mother of six children, had been in labor about four hours; the membranes ruptured a few minutes before I arrived. I applied my abdominal bandage, and in eight minutes labor was completed. In her six other confinements the times from the rupturing of the membranes to the completion of labor were not less than six hours.

CASE VIII.—Primipara, had been in labor four hours when membranes ruptured. I applied my abdominal bandage, and labor was completed in twenty-eight minutes.

CASE IX.—Multipara, mother of four chil-

dren. I applied my abdominal bandage before the completion of the first stage of labor, in order to relieve an annoying pain in the small of the back. Therefore I did not make my bandage as tight as I do in the second stage of labor. In forty-five minutes the membranes ruptured, and I tightened the bandage, and labor was completed in ten minutes.

CASE X.—Primipara, had been in labor but one and a half hours when I applied my abdominal bandage. The membranes ruptured immediately after I applied the bandage, and labor was completed in twenty-five minutes.

Now, in conclusion, let me repeat the benefits that may be derived by the use of an abdominal bandage during labor. By applying it during the first stage of labor we do away with the restlessness so peculiar to the first stage. Last, but not least, we shorten the duration of the second stage of labor, and by so doing we deliver the woman before she has worn herself out by contracting the muscles of the chest to stimulate the abdominal muscles to help the uterus expel its contents.

#### ON LOBELIA INFLATA IN ASTHMA.

The employment of lobelia inflata against asthmatic disorders has of late become obsolete, owing to the alleged inertness of the drug in the mentioned affection. DR. NUNES writes to the *Bulletin Génér. de Thér.*, No. 4, 1886, that he feels convinced that the failure of lobelia in asthma is caused solely by using the drug in too small doses. Trousseau and Pidoux prescribed 2 to 25 drops of the tincture three to four times daily, Dujardin-Beaumetz 20 to 50 drops, Gubler 1 to 2 fʒ, and Torres Ilomen even 2½ fʒ with very satisfactory results. No other clinician has ever employed the drug in so large a dose as Ilomen for fear of causing untoward symptoms or even poisoning. Nunes's practice of exhibiting the tincture of lobelia in doses of ½ to 1 fʒ, without having ever met with an accident, shows how little the above-mentioned fears are justified. In order to intensify the expectorant action of lobelia, Nunes combines it with benzoate of ammonia. His results were very encouraging. The following cases are alluded to in Nunes's communication:

A man of 56 years of age was suffering for a year from strong dyspnoea and coughing, interfering with his sleep. On auscultation whistling and bellows-sounds were heard.

Heart and blood-vessels were normal. Nunes prescribed

R Tinct. lobeliæ, fʒiv;  
Ammon. benz., ʒiiss;  
Aquæ dest., fʒvii. M.

S.—A tablespoonful every two hours.

Later the quantity of lobelia was doubled; the patient recovered completely.

A man 24 years of age suffered for three years from dyspnoea and cough. The vascular system was normal, but the liver was enlarged. The latter condition was removed by giving the patient

R Calomel, gr. viii;  
Pulv. rad. rhei,  
Sacchar., aa gr. vii.

S.—Take before retiring.

Later the following was prescribed:

R Tinct. lobeliæ, fʒv;  
Ammon. benz., ʒiiss;  
Aquæ dest., fʒvii. M.

S.—Tablespoonful every two hours.

After three days, cough and dyspnoea had decreased. Nunes then ordered:

R Terpene, gtt. 15;  
Mixt. gumm., fʒvii.

S.—Tablespoonful hourly.

As the condition of the patient grew worse, Nunes resorted to the dose of 1 fʒ of lobelia in 7 fʒ of water, as given to the first patient, whereupon the patient recovered.

In two other cases, Nunes obtained the same favorable results by equally large doses of the tincture of lobelia.

#### ON CERTAIN APPEARANCES IN THE URINE AFTER THE USE OF NAPHTHALINE.

In the *Arch. f. Experim. Pathol.*, vol. xxi., part i. p. 34, 1886, PROF. PENZOLDT publishes a peculiar reaction of naphthaline in the urine, which he describes as follows: Pour a small quantity of the urine, which is to be examined, into a test-tube, and add 1 c.c. of concentrated sulphuric acid. The urine swimming above assumes at once a green coloration, which is especially clear and beautiful at the line of contact of both liquids. Gradually the green color becomes turbid, and ultimately disappears. This reaction sets in invariably after the use of naphthaline, and probably refers to the formation of β-naphthachinon.

### CALOMEL IN THE TREATMENT OF CARDIAC DROPSY.

THE striking results of Jendrassik as to the diuretic action of calomel in the treatment of dropsy, especially of cardiac origin, have already received confirmation. In the *Wiener Med. Wochen.* (July 10, 1886) Prof. Stiller, of Buda-Pest, publishes the details of eighteen cases of dropsy of cardiac origin which he has treated both in hospital and in private practice by the administration of calomel after the directions given by Jendrassik. His results, although he but seldom obtained the immense increase of urinary secretion reported by Jendrassik, were in their general results quite equally favorable to his. Two cases he gives in full detail, and either alone would be sufficient to prove the truth of the statement that in calomel a drug has been found whose value seems in such cases almost inestimable. Cases with intense œdema of the extremities, peritoneal and pleural effusions, enlarged and congested liver with marked dyspnoea, he has succeeded in restoring almost to health, certainly to comfort, by the administration of calomel. He has seen œdema entirely disappear, ab-

dominal and pleural effusions and albuminuria removed, an enlarged liver return to its normal size with complete relief of respiratory distress. Such results have followed the administration of calomel alone after digitalis had failed to produce relief, and also in cases where the use of digitalis, on account of the unfavorable symptoms which so frequently interfere with its action, had compelled its suspension. Dr. Stiller thinks that he is perfectly warranted in confirming in all respects the statements of Jendrassik. He believes that in dropsy of cardiac origin small doses of calomel constitute the most efficient and rapid means of relief even in cases where digitalis fails, while no other drug can in any degree sufficiently approach it to be worthy of being brought into the same category. Its action is not only exerted on the removal of the œdema, but also on the effusion of serous cavities.

The diuresis, agreeing again with Jendrassik, he found to suddenly occur on the third or fourth day after the commencement of the administration of the drug, and it is advisable to suspend its use, to be renewed again in considerably decreased doses when the diuretic action appears to be disappearing. This action in the removal of effused liquid is only to be explained by some particular facilitation of absorption by the blood, since Stiller as well as Jendrassik found that calomel so administered was entirely without influence on the heart or kidneys. In his first few cases Dr. Stiller found that diarrhoea, and in one case stomatitis, complicated his results, but in his later experience he found that the administration of opium with the calomel entirely prevented the appearance of diarrhoea, while it did not interfere with its diuretic action. According to his experience, the most marked diuretic effects have been produced from calomel without the least sign of mercurialization.

In spite of these favorable reports, calomel cannot, however, be regarded as a substitute for digitalis, since it is in no respect a heart remedy. In the numerous cases where digitalis fails or is contraindicated, and where numerous substitutes for digitalis are either not applicable or have proved themselves unreliable, according to the above authors the value of calomel cannot be overestimated. Enough has already been determined by those two authors to prove that calomel in such diseases must in future occupy a very important place. As to the more exact indications as to its use, cases in which it is most favorable

and as to whether its employment exerts any influence on the further progress of the cardiac disease, these facts must, of course, be left to future investigations. It is to be hoped that in the treatment of heart-disease calomel will receive the investigation which it without doubt seems to deserve.

#### THE COMBINATIONS OF DRUGS.

ATTENTION is drawn in an address recently delivered by Prof. Goll before the Swiss Medical Association (*Correspondenzblatt für Schweiz. Aerzte*, No. 14, 1886) to a point in the practical administration of drugs which seems hardly to have attracted the attention which it merits. The days of bulky polypharmacy have passed, and we are now more and more striving for the isolation of active principles and the administration of drugs in concentrated, isolated forms, but yet a careful study of many of the old prescriptions can teach us many points of value. The value of many combinations of drugs is well known. Many have fallen out of use, and many new combinations may serve totally to modify the character of the individual ingredients, or, better yet, to prevent the unfavorable actions of certain drugs while accentuating the influence which it is desired that they exert. Dr. Goll calls attention to several of these which are well worthy of notice, even although many of them may be known, and although constantly employed.

First, as regards the use of opium. As is well known, opium is often added to numerous medicines to render them less irritating to the stomach or intestine, or to reduce or prevent some remote reflex action. Thus vomiting produced by irritant action on the stomach is often entirely prevented by the use of opium. Oppholzer and Hasse long ago called attention to the fact that the emetic action of antimony, while not hindered by the conjoint administration of opium, was freed from the painful retching and cramps of the abdominal muscles which almost invariably follow its administration alone. So again in the administration of drugs which are absorbed but with difficulty, the conjoint use of opium, by delaying the passage of the drug through the alimentary canal, assists in its more complete entrance into the circulation. Thus salivation or the constitutional action of mercury is more readily produced by the addition of a little opium to calomel or mercurial iodide. Finally,

the addition of opium to cough mixtures as a means of dulling the irritation from the bronchial tubes, reducing expectoration and relieving dyspnoea, is well known and every day employed.

Equally important are the various purposes served by the combination of belladonna and atropine with other remedies. Thus from the time of Trousseau atropine or belladonna has been combined with opium as a palliative against the night-sweats, cough, and dyspnoea of phthisis, while again it does not seem to be appreciated that the vomiting and nausea which in so many cases follow the subcutaneous use of morphine may be almost entirely, if not invariably, removed by the combination of one part of atropine with fifteen to ten of the morphine in the subcutaneous injection. Where morphine must be given continuously nausea and vomiting may be permanently removed by the combination of atropine in the first few injections which are given. The system seems then to tolerate the morphine, and the atropine may be omitted. So also in the removal or the prevention of nasal catarrh so constantly produced by the administration of iodide of potassium. Here the primary combination of the belladonna with the potassium iodide not only assists in the absorption and more rapid production of iodism than when the iodide of potassium is alone given, but will constantly prevent the production of the nasal complication. Against salivation Dr. Goll finds that belladonna is less active, but that there is no other drug which is equally efficacious in suppressing profuse perspiration.

One of the oldest uses of belladonna is in the relief of cardialgia and intestinal colic, where belladonna or hyoscyamus extract is to be preferred to opium or morphine. The combination of belladonna or hyoscyamus with colocynth, senna, and other drastic purges, will almost entirely prevent the griping and colic which so often renders the use of these drugs so disagreeable. An old form of administration of the extract of the hyoscyamus with colocynth and aloes, or the more modern American formula of the combination of extract of belladonna with three times its weight of podophyllin with soap, is worthy of the reputation which it at present enjoys. It is well known that by means of belladonna the intestinal muscular fibres are first excited and then partially paralyzed; hence belladonna is a valuable remedy for the relief of the spastic colic which accompanies lead-poisoning.

Another use of belladonna which does

not seem to have attracted sufficient attention is in its administration as a cardiac stimulant. The following statement of Luchsinger deserves to be widely known: "If the heart is brought to a stand-still, whether by chloroform or potassium salts, by gallic or oxalic acid salts, by apomorphine, quinine, zinc, or poisonous mushrooms, atropine will always succeed in the commencement of the paralysis in restoring the action of the heart." Again, the combination of morphine and atropine in the proportion of twenty to one will accentuate the action of cocaine; combined with chloral, belladonna reduces the paralyzing action of the former on the heart, while, according to Bert, Morat, Aubert, Doster, and Laborde, preliminary injections of atropine will greatly remove the danger of arrest of the heart in chloroform narcosis. Finally, the combination of belladonna with quinine or salicylic acid has deserved the greatest reputation in the treatment of neuralgia.

Still another use of the combination of drugs is called attention to by Dr. Goll, where the production of solubility plays the most important rôle. Mercury, as is well known, is with difficulty absorbed, and is corrosive in many solutions. The combination of mercury with albumen forms one of the most absorbable compounds. Such a solution is easily prepared by warming a solution of one of the haloid salts of mercury in the presence of a soluble albuminate. Many other additions might be made to this list of useful combination of drugs, but enough has already been said to call attention to the useful purpose which may often be served by the judicious combination of drugs, and to teach us that we must not entirely neglect the teaching of the older therapeutists.

#### THE THERAPEUTIC INNOVATIONS IN DIPHTHERIA.

THERE are professional men who regard the search for specific, or, in fact, for any other remedies against the infectious fevers, as absolutely futile, because none can, in their estimation, ever be found. Others again claim that a fever not only *cannot* be cured, but also *ought not* to be cured, for they declare (as did Prof. Winternitz) fever is merely a bridge for the diseased organism to the recuperation of its prior state of health, and the high temperature itself removes the etiological factors of the disease, viz., the micro-

organisms infesting the circulation. The question whether a fever can in reality be cured cannot engage our attention, as the rational school of medicine has never advanced any claims in this direction, and all of its remedial endeavors are directed solely against the sequelæ and complications of the febrile affection. The conviction of the impotency of our therapeutic resources against the infectious fevers ought, however, merely to enhance our appreciations of prophylactic measures without relaxing our efforts in the search for remedial means and ways.

In diphtheria especially it cannot be doubted that the results of treatment obtained at the present day surpass considerably those of the past, though this favorable showing is probably less to be credited to the exhibition of novel medicaments than to the more rational general treatment of the affection as the natural outcome of a better understanding of the nature and causes of infectious fevers. Still, there have been within the past year or two recorded certain therapeutic innovations in the treatment of diphtheria which, for their strikingly gratifying result, have attracted unusual attention. We beg to discuss here some of the novel procedures in the treatment of diphtheria.

Our readers will recall the simultaneous eulogy of the actual cautery in diphtheria by Dr. Bloebaum, of Koblenz, and an Italian physician, as published in the THERAPEUTIC GAZETTE in the first issues of this year. Bloebaum saved quite a number of grave cases of diphtheria by applying, in the initiatory phase of the affection, the Pacquelin cautery to the tonsils and fauces.\* Prof. Hensch, of Berlin, also tried the cautery in an almost hopeless case of diphtheritic infection,† with the result of saving the patient. Hensch resorted to chloroform, which he declared as indispensable (a fact not mentioned by Bloebaum) for the accomplishment of a thorough cauterization. Of course it was understood that this treatment could only be successful in the beginning of the disease, when, as Francotte declares, diphtheria is a simple local affection.

Bloebaum has time and again exhibited the cauterization treatment in diphtheria, and met with success in every instance where success could possibly be anticipated.

In No. 37 of the *Deutsche Medicinal Zeitung*,

\* *Schmidt's Jahrbucher*, vol. 209, p. 49.

† As reported by our special correspondent at Berlin, who was at the time asked to assist.

1886, Dr. Bloebaum publishes an accurate description and cuts of the apparatus requisite for the galvano-caustic treatment of diphtheria. At the same time he records another series of diphtheritic cases successfully treated by his plan. We abstract from this paper the *résumé* of the clinical history of a diphtheritic infection occurring in his own daughter, aged sixteen years.

The girl was taken sick in the evening of the 3d of April, under the usual premonitory symptoms of diphtheria. On the following morning the right tonsil presented a diphtheritic ulcer of a considerable size, which was immediately cauterized. In the evening the girl had no fever. On the following morning the patient presented four circumscribed deposits on the left tonsil, each of the size of a lentil. Again cauterization was performed, and still no evening fever appeared. The girl slept well, and was wholly restored on the succeeding day.

We pass to another mode of treatment, which, without any claims to a specific character, appears to have led to very gratifying results. Prof. Hofmokl, of Vienna, following the recommendation of Vogelsang, tried the peroxide of hydrogen in a number of diphtheritic cases, and advocates this therapeutic agent warmly in the *Wiener Med. Presse*, 1886, xxvii. 18, 19. Hofmokl prescribes the drug to be taken internally, as follows :

R. Hydrog. peroxide (2 per cent.), 200 parts.  
Glycer. pur., 3.0 parts.

S.—One teaspoonful every two hours.

At the same time the drug is to be exhibited as an inhalation. It is very probable that the beneficial effect derived from the use of the peroxide of hydrogen refer to its decomposition in the system, and the subsequent introduction of free oxygen into the blood.

Another plan of treatment recently proposed by Noeldechen, of Pforta, in the *Deutsche Medicinal Zeitung*, No. 33-36, 1886, is likewise worthy of attention. This author recommends a carefully-executed brushing of the tonsils or fauces with salicylic acid in substance. No doubt the antiparasitic virtues of salicylic acid exhibited when the diphtheritic infection is still local and circumscribed can be very advantageously utilized. At the same time Noeldechen insists upon gargles with chlorate of potassium, or the application of ice to the neck and head. Internally he prescribes at first calomel, later quinine.

Bloebaum's actual cautery and Noeldechen's salicylic acid are obviously exhibited for one and the same reason,—*i.e.*, the sterilization of the soil whence the infection pervades the blood.

It must be left to the future to decide whether these therapeutic innovations, which, as far as can be judged from isolated trials, appear actually to possess certain advantages, will ever become popular with the majority of practitioners.

#### ANDERJOA, A SO-CALLED SPECIFIC FOR DYSENTERY.

FOR many years in the island of Mauritius a remedy has been known under the name of "*mauvais*" which has enjoyed the reputation of being a specific for dysentery. Dr. Clarenc has recently found that the active ingredient of this remedy is the *anderjoa* or *anderjou* plant, a native of that island, and he publishes in a letter in the *Bull. de la Soc. Méd. de L'Isle Maurice* the manner in which this remedy is prepared. One pound of the dried *anderjoa* plant is reduced to a fine powder, and twenty tablespoonfuls of this powder are mixed with a tablespoonful of *anderjoa* powder, previously roasted, together with a tablespoonful of arrow-root, and the whole divided into ten equal parts ; each one of these is taken daily in an infusion. The *anderjoa* is the seed of a member of a group of *apocinaceæ* of the species *Hollarrhena*, and is known as the *hollarrhena antidysenterica* described by Waring in the *Pharmacopœia* of India in 1868, p. 137. Its bark has been previously imported into Europe, and is known under the names *cadoga pala*, or *pala* or *telli-cherry bark*. Its seeds have from time immemorial been regarded as tonic, antifebrile, and above all antidysenteric. Unfortunately, however, this plant has often been confounded with other species, and as a consequence it has fallen into discredit. According to Drs. Lesur and Anteleme, the *mauvais*, or as it is also known, the *lagravelle*, remedy has the following formula :

Anderjoa powder, 10 parts ;  
Arrow-root powder, 5 parts ;  
Magnesia,  $\frac{1}{8}$  part ;  
Benzoin,  $1\frac{1}{2}$  parts. M.

Boil for two or three minutes in five hundred parts of distilled water, filter through linen, and cool.

S.—Dose, two or three wineglassfuls of this infusion taken on an empty stomach one or two hours before meals, while the whole is to be taken in twenty-four hours.

On the third day of treatment benzoin is to be replaced by powdered red cinchona bark, and on the sixth day anderjoa powder is to be roasted before being powdered, and may be also mixed with a little alum.

According to the observations of Dr. Lesur, this remedy is especially useful in chronic dysentery, especially when the discharges have become purulent. It should not, according to this author, be administered until the use of ipecac., calomel, and opium have failed to prevent the transition of the acute into the chronic stages of dysentery. Dr. Clarenc also adds a number of cases which seem to demonstrate the efficacy of this medicament in the chronic forms of dysentery. As it seems to be already an export, it is to be hoped that it will be subjected to further study and its exact value determined.

#### PILLIGANINE A POISONOUS ALKALOID OF BRAZILIAN LYCOPODION.

PILLIGANINE is the active principle of pilligan, a variety of lycopodium common in Brazil and known under the name of lycopodium saurus. It has been prepared by M. Adrian (*Comptes Rendus*) in the following manner: The powder of the pilligan is treated by boiling water and evaporated to a soft extract, which is dissolved in alcohol. This alcoholic solution is then decolorized by the subacetate of lead, of which the excess is precipitated by the addition of milk of lime. It is filtered and neutralized by tartaric acid, filtered a second time, the alcohol distilled off, and the residue dissolved in water. It is finally filtered again, rendered alkaline by the carbonate of sodium, and shaken with chloroform. After evaporation the chloroform solution deposits a yellow precipitate, which is purified by a renewed treatment with the carbonate of sodium and chloroform. According to Houdé (*Répertoire de Pharm.*, July, 1886), pilliganine in the freshly-precipitated condition has a vinous odor, possesses an alcoholic reaction, and if a rod which has been dipped in hydrochloric acid is approached to it, it disengages whitish fumes. It is soluble in alcohol and water and chloroform, and slightly soluble in ether. It gives with sodium phosphomolybdate a yellowish-white precipitate; a pale brownish with potassium iodide; a white precipitate with tannin, and a very copious white clotty precipitate with potassium mercury iodide; with picric acid, after some time, a yellowish

crystalline precipitate; with mercuric chloride and platinum chloride no reaction. A few experiments have been made with this alkaloid on animals by Dr. Bardet, which have simply served to prove that it is a powerful poison with a marked emeto-cathartic action. According to the *Lancet* (July 24, 1886), M. Laborde recently presented to the Paris Biological Society a note from M. Bardet on the action of pilliganine, one of the alkaloids of the pilligan. It is stated to be a convulsive poison with a strong emeto-cathartic action. M. Brown-Séquard remarked that it must therefore be an exception to the rule, for all known convulsive poisons were devoid of action on the digestive canal. M. Grimaux explained that the convulsive effects had been obtained from the alkaloid, while the gastrointestinal effects had been produced by an infusion of the pilligan, so that it was not clear that the infusion contained the alkaloid; indeed, it might have contained some other alkaloid belonging to the same plant. As far as we can learn no further investigations have been made with this drug, which from its energy certainly is worthy of study.

#### Reports on Therapeutic Progress.

##### THE TREATMENT OF THORACIC ANEURISM BY A NOVEL METHOD.

MR. RICHARD BARWELL reports in the *Lancet* for June 5, 1886, a case of a man 39 years of age, with a syphilitic history and early intemperance, in whom there was an aortic aneurism springing from the lower or concave part of the arch, and progressing above, forwards, and backwards. In this case ligation of the vessels was evidently out of the question, and he was treated by rest and restricted diet, together with iodide of potassium, for a few weeks, and with small doses of aconite and salicylate of atropine. At first the tumor diminished in size, and then began a period of exacerbation, the cough became worse, and the tumor increased both within and without the thorax. The patient was now in a very critical state, although the lungs emitted very little air, in places none at all, the cough was very painful and constant, and expectoration purulent. In considering the cause of failure of the various surgical operations employed in the treatment of thoracic aneurism, it occurred to Mr. Barwell that if the area of galvanic action in electrolysis could be increased or the clots on foreign

bodies rendered harder and more stable, a successful result might be hoped for. This result Mr. Barwell thought might be effected by introducing into the aneurismal sac a steel wire arranged to lie in wide coils, then by passing along it a carefully-regulated galvanic current. In this way both the preceding methods might be combined, and a somewhat similar procedure was employed in his case. In the mechanical arrangement, however, there was a little difficulty. An ordinary trochar and canula, such as have been hitherto used for passing wire into sacs, was evidently unfitting on account of its conducting power. A tubular needle of vulcanite, with a steel tip and several other devices, were procured and rejected. At last a tube of ivory, sharpened like a hypodermic needle, was accepted as the most feasible arrangement. On March 2, the skin being rendered insensitive by the injection of cocaine, a fold was pinched up, and a little incision made from within outwards over the tumor; the ivory needle was then thrust in without difficulty, and about ten feet of the finest steel wire passed into the sac. The wire, having been first wound on a wooden cylinder half an inch in diameter and being of the best steel, must, after being paid through the needle, coil itself up again in the sac. Dr. Murray undertook the management of the galvanic arrangements, and he gives the following short account: "The wire was connected with the positive pole of an eight-celled Grenet's battery. The negative was applied to the upper dorsal region a little to the left of the middle line. Between the electrode and the skin was interposed a piece of amadou about a foot square, thoroughly saturated with hot water. A galvanoscope and a voltmeter (Gaiffe's) were included in the circuit. The resistance in the voltmeter was so great that the strength of the current did not exceed four milliampères. Twenty cells of a Coxeter's 'practitioner's voltaic battery' were therefore added to the Grenet battery, and the current strength was raised to about nine or ten milliampères. At this level it was maintained during the operation. The current was passed for an hour and ten minutes. Some redness of the skin was caused by the negative pole, but no indication of irritation at the place of puncture." For twelve hours signs of consolidation were absent, or nearly so; but at the end of that period the pulsation seemed considerably more distant and the tumor much harder, and this change rapidly increased. The lungs began to unload themselves of their accumulated pus and

muco-pus; expectoration, very difficult previously, became easy and somewhat copious, showing decrease of pressure on the bronchi. But on March 5 (fourth day of operation) a new tumor appeared to the right of the sternum, and rapidly increased. The man also became weaker. He died on March 9, a week after the attempt, partly from exhaustion, and partly, as it appeared, from rupture of this second sac.

At the post-mortem it was found that the interior of the bronchi were of a deep purple color; in places the mucous membrane was nearly or entirely absent; the substance of both lungs airless and tough, sinking in water, but not from inflammatory consolidation. The very large aneurism occupied the concave aspect and lower part of the front of the first and second part of the aorta; it had eroded a portion of the sternum and the ribs; the anterior portions of the almost solid lungs, more especially of the right lung, seemed to form part of the sac. On opening the aneurism, it was found to consist of two parts,—a left portion, much the larger, and a secondary or right portion, which seemed to have recently increased in size, and which, where the lung formed a part of the wall, had burst, and given exit to two pounds and eight ounces of blood, which was found in the right pleura. The left portion contained large wide coils of steel wire, each of which was surrounded by a pretty thick coat of firm colorless fibrin, strongly adherent to it at many places,—that is to say, wherever the metal was in contact, or within a moderate distance of the wall, the wire was bound to the sac by this fibrin, thus greatly increasing its strength and resisting power.

Mr. Barwell points out that his attempt was evidently too late; the man's lungs were already all but useless. The conformation of the aneurism also was unfortunate, in that it possessed a secondary sac, into which the wire could not pass. Not a new one developed after the operation, for the man stated in writing three days before his death that the tumor to the right of the sternum had existed two years previously. The endeavor to save life was by these circumstances frustrated. But consider what the condition of things found in the large sac means. Evidently it means that by passing a galvanic current not merely along two or three needles, which are afterwards removed, but along some feet of wire, which is left *in situ*, we have a device by which a considerable quantity of hard, firm, and persistent clot can be produced in

large quantities, even though, as in this case, the aneurism may be close to the heart. Mr. Barwell believes that if a galvanic current and coils of wire are to be of service in such cases, they will only be so when used in combination, after the manner thus illustrated.

#### THE INFECTIOUS CAPACITY OF CHRONIC GONORRHOEA.

NEISSER, the discoverer of the gonococci, addressed the meeting of German physicians at Strassburg on the interesting subject of the infectiousness of chronic gonorrhœa (*Centralblatt für Klinische Medizin*, April 3, 1886). He believes that the question whether chronic gonorrhœa is infectious or not cannot be answered summarily, but can solely be decided from case to case by repeated examinations of the gonorrhœal secretion for gonococci. Examining one hundred and forty-three cases of chronic gonorrhœa for gonococci, he found the proportion of cases giving a positive result to be almost equal to that giving a negative result.

Neisser recommends as the most effective treatment nitrate of silver in a proportion of 1 to 3000-2000, or a five per cent. solution of salicylate of sodium, the remedy being best injected with a soft thin catheter, having at its point several openings. In a case presenting even on repeated examinations no gonococci at all, treatment is better wholly avoided. The internal administration of the balsam of copaiba appears to be a useful measure.

This recalls a statement of two French observers, Sinety and Hennegue (vide *Progrès Médic.*, 1885, No. 33), which is in opposition to Neisser's claim. In their experience injections of nitrate of silver were unable to kill the gonococci found in the urethritis of females. The same negative results they obtained also with permanganate of potassium, ozone-water, and even with corrosive sublimate.

#### THE SURGICAL TREATMENT OF SUBINVOLUTION.

At a recent meeting of the alumni association of the Woman's Hospital in the city of New York, Dr. A. PALMER DUDLEY read a paper with the above title (*Amer. Journ. Obstetrics*, July, 1886).

Dr. Dudley said that this condition was not particularly noticed by gynecologists, and that there was especially a paucity of histological evidence as to the nature of the condition. Retzius, of Sweden, had called atten-

tion to this twenty years ago. The reader then gave a history of the physiological processes leading to an increase of uterine tissue and to involution and subinvolution.

The terms areolar hyperplasia, chronic metritis, and subinvolution were often misapplied. Most writers gave more attention to chronic metritis (which was a misnomer) than to subinvolution. He had sought to discover the histological conditions present in this affection and would give the views of various authors. Dr. W. H. Welch, in a personal letter to him, had stated that he could find no evidence of any true inflammatory process in subinvolution. Cohnheim had reached practically the same conclusion.

The usual treatment of subinvolution by local remedies, iodine, phenol, douches, etc., even when faithfully carried out, relieved the patient only for a time; the uterus again increasing in size and the symptoms returning when the treatment was suspended. The reader believed that Emmet's operation for lacerated cervix was the best means of curing subinvolution, even when there was no laceration. He then gave in detail the histories of twelve cases of subinvolution, all of which suffered from pelvic distress and dragging, supra-pubic pain, backache, leucorrhœa, etc., the uterus being tender on pressure. Seven of these cases had laceration of the cervix; in six there was no laceration; ten suffered from dysmenorrhœa; eight from constipation and dysuria. Treatment by means of hot douches, iodine, glycerin-tampons, the tapping of cysts, curetting, etc., was faithfully carried out, and the patients were relieved, but were not cured.

After this hysterio-trachelorrhaphy was done where the cervix was lacerated; in the other cases a slender wedge was removed from the cervix, the apex of the wedge being carried deep enough to divide the circular artery. The depth of the uterine cavity was in all cases carefully measured when the patients began treatment, before the operation was done, and again some time afterwards. Of these twelve cases, there was in all a marked diminution in the length of the uterine cavity and improvement in the symptoms; in three cases, where there was displacement, the uterus returned spontaneously to its normal position; a thirteenth case, in which the wedge-shaped mass was excised, was complicated by the presence of a large fibroid; here, after ninety days of ordinary treatment, the uterus measured three and three-quarter inches (a diminution of one-quarter inch by treatment);

fifty-four days after the operation the uterus measured two and five-eighths inches, and there was marked relief from symptoms and diminution in the size of the fibroid.

#### ARTERIAL PRESSURE IN BRAIN AND FOREARM AS INFLUENCED BY VARIOUS DRUGS.

CAPELLI and BRUGIA, of Milan, have made some very interesting experiments on the blood-pressure as altered by various drugs. We condense their principal conclusions arrived at from *Schmidt's Jahrbücher*, June 22, 1886:

1. Inhalations of nitrite of amyl cause a fall in the pressure, first in the brain and then in the forearm. Besides, there are, however, some variations of pressure in both regions, which are not isochronic.

2. Morphine applied hypodermically in small doses produces at first a vascular contraction, and then a dilatation, most pronounced during sleep. The latter condition leads to an increase in volume of both the brain and the forearm.

3. Chloral causes at first cerebral anæmia on account of the decreased resistancy of the peripheral arteries; later there appears a vascular paresis, with a subsequent increase in volume of the brain.

4. Paraldehyde does not always produce hypnotic effects. Soon after application of the drug the cardiac power increases, and reaches its maximum during the deepest hypnosis. If no sleep result, this action upon the heart is less pronounced.

5. Hyoscyamine at first acts as an excitant; later the frequency of the pulse increases, while its pressure falls, until ultimately the normal state of both frequency and pressure are regained.

In a cold bath the peripheral arteries contract, the volume of the brain augments, and the pulse is first quickened and later slowed.

In a warm bath the experimenters found, contrary to the usually assumed venous stagnation of blood in the brain and a diminished vascular tension, during the entire bath a certain degree of vascular contraction and cerebral anæmia, with peripheral vascular congestion.

#### A CASE OF IDIOSYNCRASY WITH REGARD TO TANNIC ACID.

DR. J. M. WILLIAMSON reports in the *Practitioner* for July, 1886, a case of a married woman, aged 57, who had been suffering from

anæmia from hemorrhoidal bleeding, which after operation left her the subject of distressing irritability of the bladder. Previously this trouble had always yielded to a mixture containing bicarbonate of potassium and tincture of henbane and an infusion of buchu; but this medicine failing to produce any effect, Dr. Williamson administered a mixture of sulphate of atropine, the anissated solution of ammonia (German Pharmacopœia), and the infusion of uva ursi. This seemed to produce symptoms of an asthmatic paroxysm, accompanied by a short, violent, suffocative cough, and with decided mental confusion, although vomiting and nausea were absent. Dr. Williamson concluded that this peculiar effect, the responsibility of atropine having been excluded, was attributable to the tannin which is so abundant in uva ursi. The symptoms passed completely and permanently away between two and three hours. This view as to the production of these peculiar symptoms was confirmed by Dr. Williamson's previous experience in the same case, where the administration of a rectal injection of 30 grains of tannic acid in alcohol and water for bleeding from hemorrhoids produced similar symptoms to those above alluded to, although very much more severe.

So also a number of other instances. One especially where, after emptying a box containing tannic acid, she had blown into it, inhaling a portion of the tannic acid; similar symptoms were produced. It seems therefore that there existed in this patient an idiosyncrasy with regard to tannic acid. Tannin injected into the rectum, tannin accidentally inhaled, the taking into the stomach the infusion of uva ursi leaves, all were followed by identically the same symptoms, while the curious fact is also noted that the application to the skin of an ointment of galls and the administration of gallic acid internally produced no disturbance.

These points are well worthy of recollection.

#### ACTION OF SCOPOLEINE.

PIERD'HOUVY, desiring to directly compare the action of scopolamine with that of atropine, applied, as stated in *Nouveaux Remèdes*, 1886, No. 3, p. 61, in four healthy persons, atropine to the right eyes and scopolamine to the left eyes. Both alkaloids were furnished by Merck, and were employed in an equal solution (1 to 40). In the action of both remedies the observer noted a periodical simul-

aneous increase and decrease. Somewhat sooner than in the atropine eye, about eight minutes after application, the scopolamine eye presented an increase in the vertical diameter of the pupil, which, after a quarter of an hour, was followed by a return to the normal state. In scopolamine the maximum of mydriasis and paresis was reached in forty-five minutes, in atropine in sixty minutes. Twelve hours later, the pupils of the eyes treated with scopolamine became again dilated, remaining thus for three days. This return of physiological action after so great an interval is characteristic of scopolamine, and has never been observed in the case of atropine. Led by these researches, Pierd'hoy applied scopolamine in a case of chronic iritis, and obtained the desired effect without the eczematous after-effects following the atropine application, and which can only be avoided by applying cocaine simultaneously with atropine.

Pierd'hoy pronounces the mydriatic power of scopolamine as far superior to that of atropine, and advocates the employment of the former alkaloid in ophthalmological practice.

#### NEW METHOD FOR RELIEF OF RUPTURED PERINEUM.

At a recent meeting of the Medico-Chirurgical Society of Montreal (*Canada Medical Record*, June, 1886), DR. TRENHOLME read a paper on this subject, exhibiting drawings of the new method, as follows: This disease must be as old as parturition itself, and yet, beyond the adjustment of the parts, binding the knees together, in recent cases no really successful advance had been made for its cure till the late ever-lamented Dr. Sims introduced his silver suture. The operations of Baker & Brown and others were not of any real value, and perhaps the cause or nature of failure was not fully brought out till Emmet's paper upon this subject was given to the world. How much progress has been made can hardly be conceived of by those who have graduated during the last twenty-five years. Yet one of the best surgeons may endeavor to dissuade a confrère from attempting the operation, stating that "it is sure to be a failure." It is a recognized factor in the causation of subinvolution of the vagina and uterus, and its results are not limited to these organs, but that the tubes and varied ligaments share in the same mischief. It is a fruitful cause of retrolaxations of the uterus and prolapsus of bladder. Of all the marital misery and per-

sonal distress need be said nothing: these, of course, vary with the peculiarities of individual cases and the extent of the disease. There is one remark Mr. Trenholme makes as to what is known as the perineal body. Some writers have made light of its existence, because its anatomy and relations are not sufficiently definite to merit, as they think, this appellation. That every uninjured perineum has such a body is unquestionable, and the restoration of this body is *the one* object of perineorrhaphy. An operation is successful or unsuccessful, according as to whether this end of the operation is or is not attained—without it the natural support of the pelvic viscera is impossible. Not only is there apt to be hernia of the anterior rectal wall, but prolapsus of both bladder and uterus. The best success heretofore has followed Emmet's operation. His conception of the trefoil character of the surfaces to be brought together are based upon a right conception of the anatomy of the parts. The perineal body being the central, and the lateral surfaces the outside leaves of the trefoil, each sulcus represents the lateral borders of the vagina and rectum. Perfect union of these surfaces leaves but little more to be desired. In the first place, the loss of any tissue is to be avoided, and sure union by first intention the desideratum to be attained. Mr. Trenholme's operation is based upon the recognition of the immense value of the perineal body. He describes it as follows: "I denude the surfaces to the fullest extent of the parts injured. This denudation is accomplished by the removal of the covering of the parts to be denuded,—i.e., the cicatricial surface in *one* piece. For this purpose the first incision is made at the upper part where the edge of the skin coalesces with the cicatricial surface; the knife is entered at the highest point on the right side, and the incision brought down to the lowest part of the fourchette, when it is met by a similar incision on the left side. The lowest part of the angle is then seized with the forceps and carefully dissected upward, taking special care to remove the whole surface without incising the flap; this dissection is carried on till the surface represented by the original wound is uncovered. The next step is the introduction of the shield-sutures (and here I would say a word in favor of the catgut suture which I adopt). It is by far the best, as it gives the greatest possible extent of surface to surface,—much greater than can be secured by the interrupted or any other suture. Two deep sutures usually suffice, and these—whether

silver, silk, or catgut—are passed in and secured by clamp shot upon an ivory shield. The first suture should be inserted low down, and about three-quarters of an inch from the edge of the wound. It must be passed under the denuded surface so as not to appear, and brought out on the opposite side at a point corresponding to that of insertion. The second deep suture is similarly introduced higher up. The last deep suture should catch the flap, and the interrupted suture will do for this. The edges of the wound are coapted by horse-hair sutures, and the upper part of the flap and around on the right and left side are secured by catgut sutures; this leaves the united surfaces in the shape of the letter T. The vaginal surface is perfectly covered, and in no way can a drop of fluid enter the wound or interfere with union by first intention. There is very little pain, inasmuch as the deep shield-sutures allow of distention. Interrupted sutures should not be used. Where the rupture extends into the rectum, the flaps are carefully brought together by a running catgut suture, and the operation completed as in this case. The objection to all other operations was that it left the vaginal incision open, which, sometimes, therefore, interfered with union by first intention. By my method this is now impossible, and when catgut is used the results of the operation leave absolutely nothing more to be desired. The following points are gained: Perfect union, perfect restoration of the perineum, no loss of substance, and no after-fever worthy of the name."

#### NOTE ON THE PHYSIOLOGICAL ACTION OF TANGINA.

QUINQUAUD, reviewing the action of tangina, the drug used by the inhabitants of Madagascar for ordeals, attributes its principal effects to its influence upon the central nervous system (*Centralblatt für die Medicinischen Wissenschaften*, April 24, 1886). Applied to frogs the drug suspends the voluntary motions, heightens the reflex excitability, and causes clonic and tonic convulsions. Later, symptoms of paralysis set in, though the excitability of the muscular apparatus and of the peripheral motor nerves remains intact. Ultimately, however, the peripheral nerves appear as if affected by a curare-poison. In dogs the convulsions are preceded by vomiting, diarrhoea, and tenesmus. The working power of the muscles remains normal until death ensues. Respiration is first quickened, later slowed; the frequency of the pulse is

transiently heightened, then lowered; the blood-pressure is at first raised, and later depressed through cardiac weakness. The poison is thus seen to affect simultaneously circulation and respiration, the cardiac action outlasting respiration. Death ensues through respiratory failure.

Quinquaud administered an extract of tangina in doses of 1 to 1½ grains in various affections, and arrived at the conclusion that the drug could be utilized in paralytic affections of a toxic nature and in tremor and atony of the intestines. In two cases of urinary incontinence the drug led to a distinct improvement. If headache, nausea, vomiting, or a sensation of weakness sets in, the drug is to be suspended.

#### THE TREATMENT OF ORCHITIS AND EPIDIDYMITIS.

There is such a diversity of opinion as to the best treatment of orchitis and epididymitis the result of acute gonorrhœa, that the results obtained by MR. FREDERICK W. LOWNDES (*Lancet*, July 24, 1886) for the last eleven years in the Liverpool Lock Hospital are of considerable importance. The plan practised in this hospital is almost invariably that introduced by Mr. Furneaux Jordan in 1869, namely, by painting the affected testicle with a strong solution of nitrate of silver (two drachms to the ounce), at the same time enforcing strict rest in bed, and supporting the inflamed organ upon a small pillow so as to prevent it hanging down. Mr. Lowndes has invariably employed the same treatment, and in eleven years has treated two hundred and sixty-nine cases. He has always found his plan highly successful. The acute pain often amounting to agony is soon subdued, and in the majority of cases the organ returns to its normal size in the course of a few days. Sometimes a second painting is necessary, but this then suffices. The same plan of treatment has also been used by him successfully in private practice. When the patient cannot be induced to take absolute rest in bed, and when the patients are compelled to follow their usual occupations, the recovery must obviously be slower, as it is not possible by suspensory bandages or by means of handkerchiefs, however skilfully applied, to insure such perfect rest as when the patient is lying in bed. While the rest is an important item in the treatment, it is not by itself sufficient to effect a cure. The immediate effects of the nitrate of silver in allaying the pain are most marked, though for obvious

reasons the nitrate must act more powerfully while the organ is in a state of quiescence than when constantly active.

#### ON THE ANÆSTHETIC ACTION OF SUBCUTANEOUS INJECTIONS OF COCAINE.

WÖLFLE has made some very interesting experiments with the view to ascertain the anæsthetic effects of hypodermic applications of cocaine (*vide Heitler's Centralblatt*, April, 1886, p. 172). He found that an injection of about  $\frac{1}{2}$  drachm of a five per cent. solution of cocaine produces within two to three minutes an anæsthetic condition lasting for twenty to twenty-five minutes. The region of complete anæsthesia had a diameter of two to three centimetres, while the adjacent skin was in a state of semi-anæsthesia for a distance of two to three centimetres. Further injections widened the sphere of anæsthesia. Needles introduced into the skin to a depth of three centimetres were not felt.

Wölfler employed these injections practically for the extirpation of small tumors, removal of foreign bodies, opening of abscesses, and similar minor operations. In larger incisions the injections are best made at both termini of the incision. Wölfler obtained excellent results with cocaine injections in neuralgias, especially of a strictly localized nature. Though not meeting himself with any accident in the employment of cocaine, Wölfler advises nevertheless to be cautious in its use, as Heyman had recently observed a severe intoxication after its application. (Cocaine had been applied by the brush to the larynx of a boy 10 years of age previous to the removal of papillomata, whereupon a state of apathy set in which lasted for five hours.)

#### THE ALLEGED POISONOUS PROPERTIES OF THE COMMON PARSNIP.

Two of the contributions from the department of pharmacy in the University of Wisconsin are devoted to the subject of the alleged poisonous properties of the root of the common parsnip (*Pastinaca sativa*), when growing wild. It appears to be a popular belief in some parts of the United States that if the edible roots of the cultivated parsnip remain three years in the ground they revert to the wild form, and then possess poisonous properties. MR. J. T. BENNETT failed, however, to separate from wild roots any principle that produced poisonous symptoms when ad-

ministered to the lower animals, and MR. WELLS gives direct testimony that he has eaten, both cooked and raw, roots from a parsnip patch that has been allowed to run wild for probably half a century. It is concluded, therefore, that the frequently-reported cases of poisoning by wild parsnip root ought to be attributed to one or other of the umbelliferous roots resembling it which are known to possess poisonous properties.—*Pharm. Journ.*, July 31, 1886.

#### ON ANÆSTHESIA PRODUCED BY COCAINE THROUGH INTERVENTION OF ELECTRICITY.

We are indebted to our Viennese contemporaries, the *Wiener Med. Blätter* (No. 6, 1886) and the *Centralbl. f. Therapie* (No. 4, 1886) for the description of Wagner's interesting method, which we have already shortly alluded to in a previous issue, of producing anæsthesia of the skin by the combined action of cocaine and electricity. Wagner utilizes the so-called cataphoric property of the galvanic current, which enables him to render the skin anæsthetic over any wanted area, provided the epidermis is intact. The cataphoric action of the galvanic current depends upon its power to direct liquids contained in a porous receptacle from the anode to the kathode. The living tissue represents such a porous receptacle, and is well adapted to execute this cataphoric action of the current. The quantity of liquid moved in a certain unit of time is the greater the stronger the current and the poorer the conducting quality of the liquid is.

The application of this peculiar action of the galvanic current for the introduction of medicinal agents into the organism has been previously attempted by other experimenters without having furnished very encouraging results. This failure Wagner attributes to the choice of the employed drugs, which probably did not fulfil the requisite of being active in very small quantities without demanding a strict fixation of the dose. Cocaine answers fully to this requisite. Wagner's *modus operandi* for the production of anæsthesia consists in applying a flat electrode invested with leather or flannel and saturated with a solution of cocaine to the skin; this electrode is made the anode of a galvanic current of a medium strength. After a few minutes the electrode is removed, when the entire surface of the skin which was covered by the electrode will be found to be completely anæsthetic. The degree of anæsthesia is propor-

tional to the strength and the duration of the current; its duration is from ten to fifteen minutes.

The larger the area to be anæsthetized the greater must be the strength of the current. Wagner uses a circular anode-electrode of two and a half centimetres and a five per cent. solution of cocaine with a current of six milliampères for four to five minutes. For the head and neck especially this strength suffices, while for the trunk and extremities currents of ten to fifteen milliampères should be employed.

If a deep anæsthesia is intended Wagner recommends to place the kathode diametrically opposite to the anode.

The quality of the cocaine solution influences the cataphoric effects only inasmuch as these are the greater the poorer the conducting quality of the solution is. A stronger solution is a better conductor than a weaker one, and therefore less eligible than the latter. On the other hand its higher degree of concentration warrants effects not anticipated from the use of a weaker solution. It has not yet been ascertained whether or not the stated advantage and disadvantage equalize each other.

Wagner's practical experience with the procedure is limited though encouraging. Thus in a small operation he became convinced that incisions could be made through the entire thickness of the cutis without occasioning any pain. If the anæsthesia does not penetrate deeply enough, the deeper parts of the wounds can, as suggested by Wagner, be rendered anæsthetic by applying the cocaine solution directly to them.

In the conclusion of his paper, as appearing in the above-quoted journals, Wagner refers to Corning's observation, viz., that the effect and duration of a cocaine injection can be increased if the Esmarch bandage is applied a little while after the injection. Applying the cocaine by aid of electricity, Wagner confirmed Corning's observation, and found that the anæsthesia could be extended over one-half by the use of the Esmarch bandage.

#### *BROMIDE OF POTASSIUM AND LOTIONS OF ETHER FOR SUNSTROKE.*

DR. C. H. HUGHES publishes in the *Weekly Med. Review* (St. Louis, July 17, 1886) a note in which he calls attention to the great value of bromide of potassium in this affection, by the mouth when it will be so taken, or by the rectum when the patient cannot be induced to

swallow it. According to Dr. Hughes, it brings about more speedily in the gravest cases the mental recovery of the patient, and averts the serious brain sequellæ, immediate or remote, of this always serious affection. Dr. Hughes claims that the acute insanity of sunstroke much sooner subsides under its use than from the cold treatment alone, and that the cold treatment ought always to be suspended as soon as the patient comes to himself and appears drowsy and feels chilly. His plan is to give from sixty to one hundred and twenty grains during the first hour, and sixty grains every hour or thirty grains every half hour, largely diluted in peppermint water; sulphuric ether freely to head and spine and fanned away till six ounces are used; ice at the same time to arms, wrists, abdomen, over the heart, legs, etc., and, in extreme cases of comatose collapse, ice-cold water into the bowels with ginger and capsicum, but ordinarily moderately cold water with two hundred grains of bromide of potassium.

He reports that a recent violent case with maniacal delirium, fear of being murdered, and requiring six men to hold him down, was subdued, as all his previous cases have been, by the free use of bromide of potassium, ice, and ether, passing into a tranquil sleep with soft and regular pulse and respiration within three hours after the beginning of the attack.

The man was a laborer, struck while at work in the street. He had drunk some that morning and more the night before, but was not intoxicated. He was thirty years old, and married.

The patient took altogether two hundred and forty grains during the first twenty-four hours, and will take two hundred and forty more, at the rate of ninety grains a day, before treatment is discontinued.

He was allowed some ginger ale when he began to complain of being cold, and ice removed and dry clothes put on him.

The remote consequences of sunstroke are very serious in various chronic forms of head trouble, especially in insanity, and few persons who have once had a sunstroke can ever after well tolerate heat. The chief and greatest value of the bromide of potassium treatment, at the time of the attack, is in averting these consequences.

Of course, atropine and iodide of potassium are not to be disparaged, and may be blended with the bromide treatment. And muriate of ammonia and aromatic spirits of ammonia may immediately follow it.

ON THE POISONS EXISTING NORMALLY  
IN THE ORGANISM AND THE TOXIC  
NATURE OF THE URINE IN  
ESPECIAL.

The GAZETTE has already reviewed the very interesting investigations of several French observers, especially of Gautier, concerning the ptomaines, and we feel convinced that also the present discussion of the subject, abstracted from BOUCHARD's paper, as appearing in the *Gaz. Heb.*, vol. xxxiii., Nos. 13, 14, pp. 205-221, 1886, will be read with interest. Among the chemical constituents of the animal organism there are some which possess distinctly toxic properties. Man, under normal conditions, avoids intoxication from this source by the following procedures: 1. Several of the poisons are being destroyed within the various organs by oxidation processes; 2. Others are being retained or destroyed by the liver; 3. The majority of them is being eliminated from the system by various channels.

Bouchard endeavored to measure the quantity of toxic matters contained normally in the urine, assuming as the unit of measure (*unité toxique*) a quantity corresponding to the dose fatal to each kilogramme of body weight of a rabbit. In these investigations the normal human urine, after being neutralized by bicarbonate of sodium, was rapidly injected into a vein.

The injection of 10 to 15 c.c. (2 to 3 drachms) of normal human urine caused the following appearances: The pupils contract very strongly, and respiration becomes hurried but shallow. Soon the motions of the animal grow weak and uncertain, and urination increases. Death ensues finally under reduction of temperature and of reflex activity. Heart-beats and contractility of the smooth and striped muscles continue even after death has set in. If in the beginning of the coma the injection of urine is stopped, the animal recovers rapidly.

The fall of temperature caused by the injection Bouchard explains as caused by a diminished generation of heat; injection of water, on the other hand, increases the production of heat.

It is not a little interesting to find that, according to Bouchard's calculations, the quantity of poison eliminated by a healthy man during two days and four hours is sufficient to poison himself.

In another communication, Bouchard compares the poisonous substances of the urine eliminated during sleep and in the waking

condition. He found that the nocturnal urine, in spite of having a higher specific gravity than the diurnal secretion, contained only one-half to one-quarter of the poisonous quantity of the former. The urine reaches its toxic minimum about the time of one's falling asleep, and its maximum sixteen hours later.

The question naturally presents itself, whether the higher toxic character of the urine voided during daytime entertains any relations with the ingestion of food. During alimentation potassium and the alkaloids allied to the peptone group are being resorbed, and it is possible that the toxic substances eliminated by digestion in the liver enter the circulatory channels by means of another resorption. The day urine contains twice as much potassium as the night urine. Still, Bouchard showed that only one-fifth of the poisonous substances of the day urine and only one-third of the poisonous substances of the night urine could be attributed to the potassium salts. And still less can the other mineral salts of the urine be considered in this direction. If, however, the ingestion of food were the only factor in question, the maximum and minimum of the poisonousness of the urine would be directly opposed to each other as far as time is concerned.

The day and night urine, besides showing quantitative differences, present also some qualitative variations. The night urine causes cramps and convulsions; the day urine is a narcotic, and shows little or no convulsive action. Bouchard even found that both urines were antagonistic to each other, the one being the antidote for the other.

Bouchard's researches not yet being closed, we hope to have another opportunity of resuming this interesting topic.

URETHAN AS A PHYSIOLOGICAL ANTI-  
DOTE TO STRYCHNINE.

Some very interesting observations have quite recently been made by PROFESSOR COZE on the subject of the physiological effects of urethan, and more particularly on its antagonism to those of strychnine. The first point is its extreme tolerance when injected subcutaneously, or into the peritoneal cavity. 8 to 10 grains so injected did not set up any local irritation in the frog, nor did 30 grains in the guinea-pig. No symptoms of gastric irritation were produced by from 80 to 100 grains given by the mouth in rabbits. The effect of the drug on the blood appears

to consist in an increase of the amount of oxygen (four per cent.); and the nervous exhaustion which follows its use may, perhaps, be attributable to the greater difficulty with which the blood parts with its oxygen in favor of the nervous system. Its influence on the tetanus of strychnine-poisoning was shown in the following manner: A frog weighing just under an ounce was injected with  $\frac{1}{1000}$  of a grain of sulphate of strychnine (the minimum fatal dose being  $\frac{1}{1000}$  of a grain, according to Falck); and as soon as tetanus declared itself, 5 grains of urethan were injected. Four minutes later, the tetanus ceased, and the muscles became completely relaxed. The next day, to the professor's astonishment, the animal was all right again. This experiment was repeated many times, with larger and smaller doses of urethan; the effects were not so lasting with doses of less than 5 grains, but, if the tetanus returned, it could be almost instantly arrested by a further injection. A mixture of strychnine and urethan injected together gave rise to no tetanic symptoms, but rather to muscular relaxation. On the guinea-pig, the effects obtained were the same; this animal being somewhat less amenable to the action of strychnine,  $\frac{1}{8}$  of a grain of the drug was injected simultaneously into two guinea-pigs. A quarter of an hour later, both the animals being tetanized, one of them was injected (into the peritoneal cavity) with 15 grains of urethan; the convulsions ceased; the respiration coming down first to 72 and then to 40 per minute. The other animal, the check experiment, succumbed in twenty minutes to the effects of the strychnine. For a rabbit weighing two and a half pounds, the minimum fatal dose of strychnine is  $\frac{1}{10}$  of a grain. Accordingly, to one weighing three pounds, successive injections were administered, amounting to  $\frac{1}{4}$  of a grain of the sulphate of strychnine, rapidly followed by a violent attack of spasm; the animal leaped and fell down breathless, and in a state bordering on asphyxia. 50 grains of urethan were then promptly introduced into the stomach, after a few artificial respirations. In the course of a few minutes, the tetanic rigidity began to lessen, first in the hinder part of the body, respiration became deeper, and the animal fell into a quiet sleep. Two hours later, the rabbit raised its head without any convulsion, and gradually recovered. The next day, the only symptom was a little weakness in the hinder legs; and, on the next day but one, the animal had to all ap-

pearances completely recovered. The contrary experiment was also made, the urethanized animal being injected with  $\frac{1}{8}$  of a grain of sulphate of strychnine, without the production of tetanus. All the experiments were repeated a certain number of times, but always with the same result. In other experiments, he administered a mixture of 50 grains of urethan with  $\frac{1}{8}$  of a grain of strychnine, and no spasm or rigidity followed. He pushed the strychnine to  $\frac{1}{2}$  of a grain without any apparent effect; and even with  $\frac{1}{4}$  of a grain, although a few spasms manifested themselves, the animal did not die. On a dog weighing twenty-five pounds,  $\frac{1}{2}$  of a grain of strychnine was counteracted with 75 grains of urethan, and in twenty minutes the animal got up and walked away with some difficulty. The next day he was all right again. Dr. Coze suggests that clinical use should be made of the drug in conditions attended with convulsions, and more especially in cases of tetanus.—*Brit. Med. Journ.*, July 24, 1886.

#### INTOXICATION WITH CHROMATE OF POTASSIUM.

In the *Deutsche Medicinische Wochenschrift*, xii. 17, 1886, DR. GLÄSER reports the following instructive case:

A gilder, 26 years of age, disgusted with life and its trials, had made up to his mind to die, and bought for this purpose five pfennige (one and one-quarter cents) worth of chromate of potassium, which he took dissolved in water. Soon after ingestion of the drug the man drank large quantities of milk. Vomiting and diarrhoea set in very soon. In the evening the patient was visited by the physician, who found widely-dilated pupils, severe gastric pains, and an albuminous urine. After washing out the stomach of the patient, the physician ordered castor oil, injections of oil of camphor, and applications of ice to the stomach. On the following day the gastric pains had decreased, the urine remained albuminous, and contained hyaline and granular cylinders. The temperature was elevated considerably above normal. Mouth and tongue showed no signs of cauterization. Ten days later the urine was normal. Diarrhoea and elevation of temperature, however, lasted for two weeks. The patient recovered fully.

Gläser believes that the patient took at least  $2\frac{1}{2}$  dr. of the poison, and regards the recovery as remarkable, as authorities like

Prof. Naunyn, of Königsberg, claim that a few grains of the poison suffice to kill.

It seems probable that the milk drunk by the patient prevented the fatal issue.

#### **BORIC ACID POWDER IN THE TREATMENT OF GRANULAR LIDS.**

DR. JAMES L. MINOR states in the *New York Med. Journ.*, July 31, 1886, that he was led to the use of boric acid powder in the treatment of granular lids by the beneficial effect produced by this agent upon the tissues somewhat resembling the conjunctiva in this disease. He had seen granular tissue on the ear and on ulcers in other parts of the body and trunk, and observed that in the nasal cavities the thickened and swollen mucous membrane was often thinned down under the continued use of boric acid. He gives the following details as to its use :

1. *Method of applying the Powder.*—The lids being thoroughly everted, the pulverized acid is freely dusted over the exposed conjunctiva with a camel's-hair brush. The amount will, of course, vary, but in most cases of granular lids a quantity should be introduced sufficient to cover completely the parts to which it is applied. The frequency of application will vary from three times a day to three times a week—this difference depending upon both the individual and the disease. It will be safe to repeat the application as soon as the disagreeable symptoms which have been relieved by the remedy begin to appear again.

2. *Effects produced by the Powder.*—Its immediate effect is to produce a burning, gritty sensation, with some pain, lasting for five or thirty minutes, and a free serous discharge, after which relief is experienced, and the lids feel freer, lighter, and smoother than before its use. This beneficial effect lasts for a period varying from a few hours to several days. The conjunctiva at times shows reduction in swelling and thickening as soon as the irritation following its use has passed off. This is, however, more noticeable after the remedy has been used for a week or more, when perceptible thinning of the conjunctiva is observed, and clearing up of the cornea if pannus be present. When boric acid powder is applied to succulent tissue or a swollen mucous membrane, a free serous discharge quickly appears, which lasts for ten or twenty minutes. This discharge occurs largely at the expense of the volume of the tissue to which it is applied, and is followed by a shrinkage of the same. This is best illus-

trated in the nasal cavities, when they are closed or nearly so from swelling of the mucous membrane. A short time after the use of the acid the passages become clearer and freer, and this is noticeable to the examiner as well as the patient. This serous flux is probably of an osmotic character. Its escape relieves succulent tissue of its superabundance of serum, thereby causing contraction, which facilitates a healthier circulation and better nutrition. Its action as an irritant is in the same direction, and is especially instrumental in the cure of corneal affections. The power possessed by boric acid of restraining micrococcal development, of diminishing diapedesis, of lessening the amoeboid movement of leucocytes, and other tissue and chemical changes which it produces, are factors which enter into the theory of its action. When the powder is applied to a granular conjunctiva, it not only covers the entire membrane, but enters the cracks and crevices between the granulations, and brings about the changes indicated upon the conjunctiva as a whole and upon the granulation individually.

3. *Cases suitable for and Facts governing its use.*—Dr. Minor has used boric acid powder in all forms of granular lids, and in most varieties of conjunctivitis, with benefit. He thinks, however, that the papillary form of granular lids is most amenable to its influence. Pannus in every instance has been markedly improved, and in many cases cures have been effected. In ophthalmia neonatorum some cases have received benefit, but he relies but little upon the powder in purulent cases. On the contrary, it acts best when the secretion is scanty and serous. He has often noticed that the conjunctiva became less tolerant of its action after the powder had been used for three or four weeks, and in such cases the treatment has been changed with success. Boric acid in this particular is similar to other agents in general use for the treatment of granular lids, for it is often noticed that a remedy will *wear itself out*, as it were, and it becomes necessary to substitute another agent for the one which has been used. Boric acid is only one of these remedies, and is no more of a specific than others, yet it is an important addition to our list of efficient remedies for a disease which is often rebellious and always obstinate and protracted. It is less painful than other remedies, its effects in this particular being often recognized by the patient, who will ask to have the powder repeated, because it is less painful and more efficient in affording relief than other agents which have been

employed. Jequirity has done much toward simplifying and hastening the treatment of granular lids, but there will always remain a large contingent in which the special condition or the general surroundings of the patient will debar its use, and in such cases as these we must resort to those remedies that are known to be of value—possibly less brilliant, but entirely free from danger.

#### TOXIC EFFECT FROM THE PERMANGANATE OF POTASSIUM.

In view of the attention which potassium permanganate is now attracting in the treatment of amenorrhœa, two cases of toxic symptoms from its internal administration, reported by DR. W. D. BIDWELL (*Boston Med. and Surg. Journ.*, Aug. 12, 1886), are worthy of attention.

The first case in which Dr. Bidwell used the drug was that of a girl 19 years of age, with advanced phthisis and amenorrhœa of ten months' standing. Dr. Bidwell administered potassium permanganate in 2-grain capsules three times daily for two days, which was followed on the evening of the second day by a moderate flow lasting for two or three days. After this the girl's general health improved, and the flow appeared the following month just as previous to the commencement of the lung-trouble. Subsequently, however, she failed rapidly and died in about two months. Encouraged in this removal of the amenorrhœa by this drug, Dr. Bidwell's partner, Dr. Brock, prescribed 2-grain capsules of the permanganate for a young lady, unmarried, 22 years of age and somewhat debilitated, who had been suffering from amenorrhœa for four or five months. After the first dose she complained of severe burning pain from the throat to the pit of the stomach, was nauseated, pulse rapid and rather weak. This was supposed to be due to some irritating article of diet, and the patient drank a quantity of milk, which eased the pain somewhat. The next morning when she took the second capsule there was a repetition of the symptoms of the previous evening, only more severe. The patient was intensely nauseated and vomited, complained of intolerable burning in the stomach and throat, was almost pulseless, completely prostrated, and did not fully recover for two or three days.

Subsequently, in the case of another young lady, unmarried, and about the same age and condition of health, who had suffered from

suppression of the menses for two months, he prescribed 1-grain capsules with the same result, pain like a flaming fire in the stomach and throat and generally symptoms of shock and collapse.

#### THE VALUE OF BORIC ACID IN VARIOUS CONDITIONS OF THE MOUTH.

Boric acid is now officinal, and justly so. It has long been used in various metallurgical and ceramic operations, and more recently its preservative power has been abundantly demonstrated. It is this antiseptic power which gives it its great therapeutic value. It is a very stable compound—one of the most stable of the acids; it is not volatile, and only exerts its action when in solution; fortunately, however, it is soluble in more than one menstruum. Up till now, its chief application has been in connection with modern surgery, where the boric ointment, lint, and lotions all hold a prominent place.

There are, however, also spheres of usefulness for it in medicine, and DR. A. D. MACGREGOR (*Brit. Med. Jour.*, July 11, 1886) calls attention to the fact that it is especially valuable in the treatment of diseases of the mouth. It is the benefit of its local action we usually wish to gain, for, though sometimes given internally,—as in irritable conditions of the bladder,—its topical antiseptic effect is more often desired. In connection with its local application in various diseased conditions of the mouth, its solubility in water and glycerin, its unirritating character, its comparatively innocuous nature, and its almost tastelessness, are greatly in its favor. More particularly is this the case in treating such conditions in children, whose oral cavities cause them so much annoyance. Speaking generally, boric acid will be found useful in all conditions of the mouth, fauces, pharynx, and nose, where there is any abrasion of the epithelium; whether it be used as a powder, gargle, mouth-wash, pigment, or confection. More definitely, it is not contraindicated in any of the forms of *stomatitis*, though scarcely severe enough for the graver varieties.

In *simple catarrhal stomatitis*, a mouth-wash, containing from 10 to 15 grains to the fluid ounce, speedily cures the condition, and exercises the same beneficial influence in the *ulcerative* form, though there, in addition to the rinsing of the mouth, a local application, in the form of the powder or pigment, should be made to the individual follicular ulcers.

The powder simply consists of finely-powdered boric acid, mixed in various proportions with starch; the pigment is a solution of boric acid in glycerin (1 in 4 or 5). In both cases, the addition of chlorate of potassium is advantageous; indeed, Mr. Macgregor usually combines it, but it is not essential.

Nothing, according to Dr. Macgregor, is at once so rapid and so efficient, in the treatment of *parasitic stomatitis* or *thrush*, as this remedy. The youngest children do not object to its application. The *oidium albicans* quickly succumbs to its influence. For thrush in children, he especially recommends boric acid, either as a mouth-pigment or as a confection. Honey and sugar have both been condemned as being inadmissible, in combination, for the treatment of thrush; but, so far as children are concerned, Dr. Macgregor considers a confection (though made with honey), which has been impregnated with boric acid, gains more by its palatableness than it loses by the tendency of the saccharine matter to further the growth of the fungus. The boric acid at once does away with this tendency. Let the pigment be frequently painted with a brush over the patches, never omitting to do it after food has been taken; or, a little of the confection, simply allowed to dissolve in the mouth; and the days of the fungus will soon be ended. He has found boric acid, combined with its salt (borax), markedly beneficial. Borax alone, however, is not nearly so good.

In *pharyngitis* and *relaxed conditions of the throat*, a gargle, containing boric acid and glycerin, with either tannic acid or alum in addition, ought not to be forgotten.

Dr. Macgregor has also found combinations of this substance helpful and grateful to the patient in the condition in which we frequently find the mouth, tongue, and teeth in severe cases of typhoid fever. The mouth is hot; the lips dry, cracked, and glued to the sordes-covered teeth by inspissated mucus and saliva; the tongue dry, or even glazed and hard, brown or black, crusted with a foetid fur. Under such circumstances, a pigment, containing boric acid (30 grains), chlorate of potassium (20 grains), lemon-juice (5 fluid drachms), and glycerin (3 fluid drachms), yields very comforting results. When the teeth are well rubbed with this, the sordes quickly and easily become detached; little harm will follow from the acid present. The boric acid attacks the masses of bacilli and bacteria; the chlorate of potassium cools and soothes the mucous membrane; the

glycerin and lemon-juice moisten the parts and aid the salivary secretion.

So much for the soft parts; a word in conclusion regarding the teeth. Few medical men have ever given a prescription for a tooth-powder (such a matter is beneath their notice), and the selection of the ingredients for the various powders and pastes in vogue for the purpose of beautifying and cleansing the teeth is left entirely in the hands of those who certainly should not know better than medical men.

A tooth-powder should possess certain characteristics; it should be antiseptic, cooling, agreeable to taste and smell, and have no injurious action on the teeth. After use, it should leave the teeth white, and a sensation of freshness and cleanliness in the mouth. As an antiseptic in this connection, nothing can displace boric acid. For years Mr. Macgregor states that he has used the following powder, and can recommend it: Boric acid, finely powdered, 40 grains; chlorate of potassium, 3ss; powdered guaiacum, 20 grains; prepared chalk, 3i; powdered carbonate of magnesia, to 3i; otto of roses, half a drop. The boric acid in solution gets between the teeth and the edges of the gums, and there it discharges its antiseptic functions; the chlorate and guaiacum contribute their quota to the benefit of the gums and mucous membrane generally; the chalk is the insoluble powder to detach the particles of tartar which may be present, and the magnesia the more soluble soft powder which cannot harm the softest enamel.

#### CRUSHING THE GRANULATIONS IN TRACHOMA.

DR. KRAMSZTYK, writing in the *Gazeta Lekarski*, advises a method of treating granular lids or trachoma which was proposed by Dr. Wicherkiewicz, and which consists of a forcible crushing of the granulations. The eyelid is everted and held by an assistant, and is then subjected to pressure between the two thumb-nails, the operator moving his thumbs to and fro so as to act on as much of the eyelid as possible. Where the granulations cannot be reached in this way, such as those situated at the canthi and on the plica semilunaris, they are pricked with a needle, and then crushed by means of a pair of forceps or some other suitable instrument. The operation is very painful, and cocaine seems to be of little use. Under chloroform, the whole of the granulations can be crushed at

a single sitting. Otherwise the length of time and the number of sittings required to effect a cure depend on the abundance of the granulations and the patient's power of endurance. Where other disease of the conjunctiva exists, it must of course be attended to, and different measures adopted. The after-treatment consists in the prolonged application of cold-water dressings to the eye.—*Lancet*, August 14, 1886.

#### COCAINE IN CATARACT EXTRACTION.

In the *Journal of the American Medical Association* (August 21, 1886), DR. GEORGE E. FROTHINGHAM publishes some cases illustrating the safety of cocaine as an anæsthetic in cataract extraction, and summarizes his conclusions as follows:

1. Cocaine relieves the operator from the embarrassments during the operation for cataract that arise from vomiting; also from the agitation of his patient which results from excessive bronchial secretion, or stertorous breathing. These are often very troublesome when ether or chloroform is used.

2. The danger to the result which often arises from nausea and vomiting after the extraction, when other anæsthetics are employed, is very surely avoided when cocaine is selected as the anæsthetic agent and is properly used.

3. The danger arising from the depressing effect of cocaine upon the nutrition of the cornea is no greater than in cases where ether or chloroform are used. The depression of the circulation, which often arises from either of them, may affect very injuriously the corneal nutrition.

4. The disturbance of the circulation of the interior of the eye, and consequent danger of panophthalmitis from this cause, is probably less in using cocaine for this operation than in resorting to general anæsthesia.

5. The danger of sepsis and consequent panophthalmitis from the use of cocaine may be avoided by using only fresh solutions.—August 7, 1886.

#### ARBUTIN.

DR. BORISOFF, of St. Petersburg, having recently examined "the pharmacological action of arbutin, a glucoside obtained from the leaves of the *Uva ursi*," by means of experiments on dogs and frogs, finds that it has a decided diuretic effect, due to stimulation of the epithelium of the Malpighian bodies and urinary tubules of the kidney, and to increase

circulation of blood through the kidneys. Though large doses of arbutin exercise a paralyzing effect on the brain of the frog, little general disturbance is caused by the drug in warm-blooded animals, even if given in considerable doses. It exercises a distinct antiseptic influence in lessening the formation of pus in cases of purulent inflammation of the bladder and kidney. Dr. Borisoff thinks this drug may be found of much use in practice. He would give larger doses than those which have been suggested by some writers,—e.g., M. Levine. He would commence with from 1 to 2 grms. (15 to 30 grains), given several times a day in powder, or dissolved in water. He has made a diligent search through the scientific journals of all nations for the literature of the subject, and has collected no less than forty-three different articles, mostly from German sources, but with a few American and Russian exceptions.—*Lancet*, July 24, 1886.

#### POISONING WITH THE BALSAM OF INDIAN HEMP.

DR. SEIFERT, of the Würzburg University, publishes in the *Münch. Med. Woch.*, xxxiii. 20, p. 347, 1886, the following history of an intoxication produced by the balsam of *cannabis indica*.

A physician of Würzburg having noted cephalalgia, coma, and palpitation of the heart in a lady after the ingestion of the above preparation, took, for the sake of experiment, after breakfast a pill containing 0.1 grm. ( $1\frac{1}{2}$  grs.) of the balsam. *cannab. indicæ* (Denzel), which has been recommended as a prompt and safe hypnotic. Half an hour later a state of excitation set in which led to frightful mental and physical exertions. The physician felt convinced that he soon had to die and could only be held by the greatest efforts of his surrounding friends. Painful muscular contraction set in, the cardiac action was weak but excited, the pupils dilated and with a sluggish reaction to light. Two days elapsed before the physician regained his prior state of health.

Seifert warns his fellow-practitioners against employing the balsam, and claims that the extract of *cannabis indica*, in Vienna at least, is justly regarded as an unreliable and dangerous preparation.

The extract of *cannabis indica*, especially the fluid preparation, as sold in the American market is not known as dangerous and unreliable, and, we may say, is rather a popular remedy with many American practitioners.

*THE MURMURS OF THE MITRAL AREA.*

At a recent meeting of the Academy of Medicine in Ireland, Dr. C. J. NIXON read a communication on cardiac murmurs of the mitral area (*British Med. Journ.*, August 7, 1886.) He referred to five varieties of mitral murmurs met with: (1) presystolic murmur; (2) postdiastolic murmur; (3) organic systolic murmur; (4) functional systolic or post-systolic murmur; (5) mitral *bruit de scie*. In discussing presystolic and postdiastolic murmurs, attention was directed to the acoustic character of the murmurs, the conditions with which they were associated, and the signs which might simulate them. Presystolic murmur might occur with: (a) a sharp clicking first sound; (b) a systolic murmur of mitral reflex; (c) partial or complete extinction of the aortic second sound; (d) a postdiastolic murmur. Postdiastolic murmur was a sign of an extreme amount of stenosis of the mitral area, and, judging from the chronometric position of the murmur, the term postdiastolic was more correct than diastolic. Having discussed the stages of mitral stenosis, as determined by the development of different physical signs, the subject of mitral regurgitant murmurs was next considered. In dealing with the systolic murmur of organic disease, a reference was made to Naunyn's murmur, which was regarded as an instance of a murmur produced by convection, owing to the peculiarities of change in structure of the mitral segments, just as Dr. Sansom had pointed out that organic changes in the mitral orifice might lead to a presystolic murmur being best heard over the tricuspid instead of over the mitral area. The systolic murmur heard over the situation of the left auricular appendix, in cases of chlorosis and such allied conditions, was not, as Dr. Balfour held, a murmur of mitral reflux, but a murmur developed in a displaced pulmonary artery. Systolic mitral murmur was developed in cases of hypertrophy of the left ventricle, associated with Bright's disease, without any organic change in the auriculo-ventricular valve; and it likewise was met with in cases of extreme dilatation of the left ventricle, as in a weak and dilated heart, and in cases of long-standing aortic incompetency. In such cases, the inadequacy of the mitral valve was due either to overstretching of the auriculo-ventricular zona tendinosa, or to a relative shortening of the papillary muscles, in consequence of the dilatation of the cavity of the ventricle. Systolic mitral murmur, of purely functional origin, was

next taken into consideration, and the conditions under which it is met with, and the special characteristics of the murmur, were dwelt upon. Dr. Nixon specially referred to the theory urged by Dr. Bramwell, to explain the occurrence of this murmur in connection with a peculiar arrangement of the muscular fibres of the heart, surrounding the auriculo-ventricular ring, constituting what was termed a muscular sphincter. The murmur was held to be produced by want of tone in the muscular fibres of the ventricle, and of the sphincter muscle, allowing such a dilatation of the orifice as to render the valves incompetent. Dr. Nixon showed that this view was incorrect, as the arrangement of the muscular structure of the heart, upon which it was based, did not exist. After alluding to certain conditions in the lung which might simulate a systolic mitral murmur, a brief reference was made to the existence of a mitral *bruit de scie*, met with in cases of aneurism of the heart, or where an abnormal communication existed between the aorta or pulmonary artery and one of the ventricles.

---

*CONCEPTION OF MALE CHILDREN AT THE TIME OF THE POST-MENSTRUAL ANÆMIA.*

DR. CAMILLO FÜRST, of Graz, publishes in the *Archiv für Gynacologie*, 1886, xxviii. 1, p. 14, a contribution to the interesting and frequently-discussed question, When and how is the sex of the conception-product determined? In the first section of the paper, which treats of "the time and causes of the determination of the sex in general," Fürst proposes certain maxims which, though not new, will interest our readers. According to the author we find a surplus of male conceptions in the working classes and country inhabitants as compared with the well-to-do people and the inhabitants of cities. Likewise, we can look for the surplus of male infants during hard times and the concomitant rise of food-prices, and before the ultimate extinction of a race. If a deficient nutrition of the procreators produces a surplus of male children, our author continues to argue, we can be certain that also the state of nutrition of the fecundated ovum, especially shortly after conception, will influence the sexual differentiation. And as after menstruation the vessels of the genital organs assume an ischæmatus character,—forming the so-called post-menstrual anæmia,—Fürst concludes that conceptions taking place

immediately or shortly after menstruation will give a surplus of males on account of a relatively bad nutrition of the fecundated ovum. To strengthen his theory the author utilizes the statements of women confined in maternities, who mostly with an astonishing certainty could remember the end of the last menstruation and the day of conception. The statistics of the mentioned institutions show a very considerable surplus of male children for the first four or five days following menstruation, and a surplus of female ones for the succeeding period.

#### A NEW VAGINAL IRRIGATOR.

The many inconveniences which attend the methods employed in private practice for administering vaginal irrigation are so objectionable that in many instances they are an absolute bar to the continuation of the process; this is largely due to the cumbersome character of the necessary apparatus. DR. JOHN W. GORDON, in the *Medical Record*, July 10, 1886, describes, however, an instrument which will do much to simplify the application of this process, and correspondingly increase its efficiency. The instrument consists of an injection-tube, which may be attached to, and operated by, all kinds of syringes—the ordinary rubber-bulb, alpha, fountain, or hydrant. This injection-tube is surrounded—a portion of its length—by a larger tube, which supplies means of ample drainage. Surrounding the intra-vaginal portion of the drainage-tube, and attached thereto, is a hollow, soft rubber bulb or tampon, conical in form, elastic and compressible, which, when the instrument is inserted within the vagina, gently and perfectly occludes the orifice of that canal, thus preventing the surplus injection fluid from escaping therefrom otherwise than through the drainage-tube, which communicates with a receptacle which is placed on the floor at the side of the bed or couch.

Thus, while this elastic and compressible tampon affords absolute immunity from leakage, it also, by means of the enclosed air-chamber, protects the sensitive vulva and perineum from undue contact with heat, thereby enabling the patient to make use of injection fluids at the highest requisite degree of temperature with entire impunity during the most lengthened period of irrigation.

Patients—without the aid or presence of an attendant—conveniently and willingly operate the instrument in an efficient manner while

occupying every variety of the recumbent position; indeed, all desirable postures are equally available, and no accessories whatever are required.

By virtue of the peculiar mechanism of this device and the simplicity of its operation the user easily controls the mechanical action of the injection fluids employed. Thus by simply compressing the drainage-tube between the finger and the exterior of the ring by which the instrument is held in place—thereby obstructing the outflow—the vaginal canal may, whenever advisable, be distended to the fullest extent by the gentle means of equable hydrostatic pressure, by which manœuvre the rugæ are thoroughly separated and the irrigating liquid finds direct access to the entire mucous surface of that organ, and may be thus retained indefinitely; while by means of the dependent position of the drainage-tube the injection fluid—obeying the fundamental law of hydraulics—wholly escapes from the vagina ere the instrument is withdrawn from its position at the termination of each period of irrigation; and hence, whatever the posture of the patient, and whatever the properties of the liquid used, perfect cleanliness of person and the avoidance of wetting or soiling clothing or bedding is insured from first to last.

The smallness of the apex of the tampon—five-eighths of an inch in diameter—renders the device no less available to the maid than matron.

#### THE INSUFFLATION OF IODOFORM INTO THE TRACHEA AFTER TRACHEOTOMY FOR DIPHTHERIA.

Were it not for the fact that after tracheotomy for diphtheria in children death is extremely common from the spread of the membrane down the trachea, the operation would be much more popular than it is at present. It is usually simple and successful enough as an operation, but the continuation of the disease in the trachea renders the final results far from satisfactory. After losing several cases from the above cause, it occurred to MR. GEORGE SHIRRES (*Lancet*, July 24, 1886) that the insufflation of iodoform into the trachea after the opening of the windpipe might do something towards preventing the appearance of membrane there, and might thereby lessen the probability of death.

The experiment proved eminently successful in two cases of which Mr. Shirres publishes full notes. In the first of these cases, that of a boy aged  $4\frac{1}{2}$  years, tracheotomy was

performed under clear indications, and two hours after the operation the inner tube was removed and a thin insufflator passed down the outer one and about 10 grains of iodoform blown down the trachea. The child had a slight paroxysm of coughing, and, to judge from the expression of his face, seemed to have experienced a rather unpleasant sensation, but there was no other result. The insufflation was repeated every four hours. The next morning the tube was found comparatively clear, but the temperature was  $102\frac{1}{2}^{\circ}$ . Being rather afraid of iodoform poisoning, Mr. Shirres stopped the insufflation, but during the day the tube got frequently clogged with membrane and had to be removed and cleaned every two or three hours. At night the insufflation was renewed and repeated every three hours with excellent effect. During the night the external tube was accidentally removed, and when summoned to the patient, Mr. Shirres found him in great distress, breathing through the wound with considerable effort. The tube was reinserted with some difficulty, and from that time the patient rapidly recovered and the tube was permanently removed on the fifth day. According to Mr. Shirres, the best time to insufflate is just after the act of inspiration. When the iodoform is insufflated into the trachea the cilia on the mucous surfaces carry the particles of iodoform upward as far as the larynx, when they are removed with the mucus through the tracheotomy tube.

#### ON THE INFLUENCE OF ANTIPYRIN ON THE ELIMINATION OF NITROGENOUS MATTERS.

The steadily-increasing utilization of antipyrin as a prompt, convenient, and innocuous antipyretic has naturally stimulated researches as to the physiological aspects of the drug. Among these the influence which this drug exercises on the tissue-changes invites, of course, our special interest.

UMBACH's experimental studies, executed in V. Nencki's laboratory at Berne, and reported in the *Archiv für experimentelle Pathologie und Pharmakologie*, vol. xxi., Nos. 2, 3, 1886, are well adapted to enlighten us in regard to the subject in question. Umbach made the observations pertaining to the elimination of nitrogen and uric acid on his own person, in order to obtain very reliable results. By rigorous dietetic measures the observer succeeded in establishing a certain normal figure for the elimination of nitro-

geneous matters, with but slight daily variations (1 dr. *pro die* at the utmost). Uric acid was determined by precipitation with muriatic acid, and the total value of the eliminated nitrogenous matters was obtained by Kieldahl's process, as modified by Petri. After ten so-called normal days Umbach took on two consecutive days 1 dr. of antipyrin each, and noted soon a general excitation, insomnia, and a peculiar burning sensation of the skin. The minimum of the bodily temperature was  $36.1^{\circ}$  C. (a reduction of  $1.4^{\circ}$  C.), and the frequency of the pulse decreased about fourteen beats per minute. It was ascertained that antipyrin, while not altering the elimination of uric acid, caused a reduction of thirty grains (corresponding to one drachm of urea) in the figures representing the total of the eliminated nitrogenous matters.

A second series of observations instituted on his own body furnishing quite analogous results, Umbach felt safe in announcing the following axiom: "Antipyrin, like quinine and other antipyretics, materially lessens the elimination of nitrogenous matters, and can therefore be said to cause a decrease in the tissue-changes of the respiratory and alimentary systems."

While antipyrin was thus shown to reduce the tissue-changes, it was proven by similar experiments that the sulphates (sulphide of calcium) cause an increase in the total of eliminated nitrogenous matters, with a simultaneous decrease of uric acid. Umbach explains this influence of alkaline salts—as in the case of carbonates—as resulting from the increased alkalescence of the juices, and the thus heightened oxidation processes in the body.

An investigation of the influence of antipyrin in fever patients instituted by Wiczowski, led to very similar results. This observer also noted a considerable diminution of the chlorides in the urine in the apyrexia produced by antipyrin, even if a sufficient amount of chloride of sodium be ingested.

#### THE TREATMENT OF A FORM OF DIARRHŒA IN CHILDREN.

There is a form of diarrhœa in children, usually occurring after weaning, and from that period to four or five years of age, which is characterized by the most horrible offensiveness of the motions. This is so marked that it is generally at once mentioned by the parents. It is commonly met with in summer, but is not strictly what is known as

infantile diarrhoea, in which disease the stools are sour, but not necessarily foetid. Probably this form of diarrhoea differs from the diarrhoea of younger infants in being caused by the growth of the ordinary bacteria of putrefaction. It is not amenable to treatment by any astringent, nor has any alteration of diet much effect upon it.

DR. JAMES BRAITHWAITE (*Brit. Med. Journ.*, July 17, 1886), however, thinks that it may be successfully treated by disinfecting the bowel contents by means of salicylate of iron, as in the following prescription, which is suitable for a child two years of age: Sulphate of iron,  $\mathfrak{v}$ i; salicylate of sodium,  $\mathfrak{v}$ i; glycerin,  $\mathfrak{z}$ iiij; water to three ounces. The iron and the salicylate should be dissolved separately, and the solutions mixed. The color is darker than port wine, and the taste not unpleasant. One teaspoonful must be given every hour, until the stools become well blackened, which happens in about twenty-four hours; or a larger dose may be administered at longer intervals. The medicine should then be given every three or four hours, and occasionally a small dose of castor-oil, to clear the bowels well out, and to get the secondary constipating effect of the oil.

In hospital practice, and amongst the poor, it is not so successful as it would be if it were possible to remove the child from the family living-room, the air of which is usually very impure, and is made worse by the smells incidental to cooking, and the presence of a sink.

#### AN EXPERIMENTAL STUDY OF THE TOXIC AND PHYSIOLOGICAL EFFECTS OF THE SALTS OF TIN.

From the study of DR. PATENKO, of St. Petersburg, relating to the action of the salts of tin, as published in the *Arch. de Physiologie*, vol. xvii., No. 1, 1886, we condense some points of general interest. The experiments made by the observer with the salts of tin on frogs, dogs, and guinea-pigs, appear essentially only to confirm what Orfila had long ago said of this metal,—viz., that it could never be used for pharmacological purposes. Patenko even doubts the vaunted anthelmintic action of metallic tin, for he found tæniæ and living ascarides in the intestinal tract of dogs which had received large quantities of tin in powder form.

The effects caused by subcutaneous injections of chloride of tin are merely to be ascribed to the caustic influence of the drug. If the latter is introduced directly into the veins

of dogs in a quantity of 1 to 2 cg. ( $\frac{1}{100}$  to  $\frac{1}{50}$  gr.) no reaction ensues. If, however, 5 cg. ( $\frac{1}{20}$  gr.) are being employed, death sets in after general trembling, tetanic convulsions, Cheyne-Stokes breathing, and opisthotonus. A post-mortem examination of the brain always shows hyperæmia, cloudy nerve-cells, with invisible nuclei and numerous ecchymoses.

Seven grains of the salt given to the dogs internally did not produce any effects at all; 15 grains caused simply indigestion and temporary vomiting.

In the experiments made on frogs it was observed that the anæsthesia which set in fifteen minutes after the subcutaneous injection of tin into the plantar region of the foot limited itself to the foot and the lower part of the thigh without ever attacking the upper one. Control experiments, consisting in the injection of simple water, showed the exclusion of mere mechanical causes in the stated phenomenon. The motility of the part remained always intact, and the animals died later of gangrene.

#### POISONING BY BISULPHIDE OF CARBON.

Poisoning by bisulphide of carbon is so rare that the following case reported by MR. WILLIAM FOREMAN (*Lancet*, July 17, 1886) may be deemed of some interest. The case was that of a man, aged 63, who had swallowed probably about half an ounce of bisulphide of carbon with suicidal intent. When seen by Mr. Foreman a quarter of an hour after his having taken the poison he was sensible, but refused to give any information. There was a strong smell of bisulphide of carbon in the room. A tablespoon of mustard with 6 ounces of warm water was at once administered, and 40 grains of sulphide of zinc directed to be taken in warm water if the mustard did not act, while afterwards 15 grains each of bicarbonate of sodium and carbonate of magnesium every 10 minutes were ordered. Half an hour later he was completely unconscious, and could not be roused, and as he had not vomited, the stomach-pump was introduced, but only a small quantity of brown-colored liquid removed. The stomach was washed out with warm water; the pupils were normal, but reacted to light; conjunctiva suffused and insensible to the touch; respiration slow and stertorous; pulse rapid, compressible, varying from 150 to 160 per minute; surface of body cold and clammy; tongue thick and furred. Two tablespoons of brandy in half

a glass of water were given through the stomach-pump, but he never rallied, and died two hours after taking the poison. At the post-mortem examination, which occurred twenty hours after death, the following appearances were noted: Rigor mortis complete; pupils normal; hypostatic congestion of dorsum; body well nourished. On opening the head the dura mater was adherent to the calvaria; surface of the brain much congested; veins gorged with black blood. Brain substance healthy. Thorax: The left lung was slightly adherent at the apex; no effusion in the pleural cavities; lungs healthy. Heart: The right ventricle contained about an ounce of dark fluid blood; walls covered externally with a layer of fat; left ventricle firmly contracted and empty. Abdomen: The stomach contained about a quarter of a pint of fluid, with flakes of lymph in it, slightly ropy, and appeared to be water and mucus. A faint smell of bisulphide of carbon was perceptible. The submucous tissue was injected, and there was a number of minute hemorrhages. The posterior wall of the stomach was much more congested (to the size of a crown-piece) than the anterior surface. There was no perforation or abrasion of mucous membrane. The spleen was small, but healthy. The liver was normal in size, and healthy. The kidneys were surrounded with a large quantity of fat; they were slightly congested, but healthy. The bladder contained about two ounces of urine, having a slight smell of bisulphide of carbon. There was less of the cadaveric smell than is usual in post-mortem cases.

#### SALICYLATE OF COCAINE IN ASTHMA.

A comparatively new method of treatment in asthma nervosum has lately been tried by PROFESSOR MOSLER, of Greifswald. It is now well known that cocaine has not only a local action on the sensory nerve-endings, but also a central one, which, at first stimulating to the nerve-centres, may, if the drug be pushed, become sedative or even narcotic. By this peripheral or central effect, it may, therefore, act in such spasmodic diseases as asthma. Early last year, Beschorner published two cases of this disease which were much benefited by cocaine. In three cases, Professor Mosler has obtained excellent results. All these cases occurred in young people of 23 to 25 years of age, and were uncomplicated by any organic heart- or lung-disease. The drug was given subcutaneously, in doses of 0.4

gramme (6 grs; this seems an exceptionally large and dangerous dose), at the commencement of the attack. The first patient, who had a bad family history as regards lung-disease, and in whom the asthma had lasted eleven years, was relieved after the third injection; two more doses caused abeyance of the attacks (which occurred previously every day) for a fortnight, when the patient was lost sight of. In the second and third cases, the treatment was more rapid in cutting short the attacks, which in the end were postponed for three or four weeks, during which the patients continued under observation. The injections caused, in one case, a slight sense of faintness and the appearance of dark spots before the eyes; but these symptoms soon vanished. It is, of course, impossible to draw from these cases any conclusion as to the permanent benefit of the treatment. Extended experience will perhaps show that the drug is only a palliative. It is in the hope of inducing other practitioners to try the treatment that Professor Mosler has published the results of his cases.—*British Med. Journ.*, July 17, 1886.

#### ADENOMA OF THE PLACENTA.

The affections of the placenta have not yet received the degree of attention to which, on account of the relations they often entertain with abortion or the progress of confinement, they are fairly entitled. Quite recently DR. KLOTZ, of Innsbruck, showed in a valuable paper appearing in the *Archiv für Gynecologie*, that the placenta is liable to an affection which has hitherto been never observed, viz., the adenoma. The following theses embody the principal conclusions of Dr. Klotz's paper:

1. There exists a true adenoma of the placenta starting from the spongy portion,—i.e., from the ectatic gland-spaces of the decidua serotina.

2. The formation of the adenoma begins with the gradual fusion of the cells of the decidua into an homogeneous protoplasmic mass resembling embryonic connective tissue and having a nucleus; besides, the glandular epithelium is reduced to a tissue of its own, from which new epithelial cells are formed.

3. The fusion mass grows by budding of its connective-tissue constituents; hence the adenoma of the placenta belongs to the connective-tissue tumors.

4. The adenoma of the placenta is liable to return after removal, unless powerfully cauterized.

5. Death and expulsion of the foetus are consequences of the adenoma.

6. The placenta is retained for weeks and months ; its spontaneous expulsion is probably impossible.

7. Klotz observed three cases of adenoma of the placenta, in none of which (after an expiration of five years) a return was witnessed. All three women enjoy at present perfect health, but of course conceive no longer.

#### *ELECTROLYSIS FOR THE TREATMENT OF URETHRAL STRICTURE.*

At a recent meeting of the Academy of Medicine in Ireland, MR. P. J. HAYES read a paper on the treatment of urethral stricture by electrolysis, the comparatively novel method practised by Drs. Robert Newman, of New York, and S. T. Anderson, of Bloomington. He gave the details of three cases, in which he had himself adopted the method with encouraging results (*British Med. Journ.*, July 17, 1886). He strongly advocated the trial of electrolysis, even for the most complicated forms of stricture. It did not at all interfere with the subsequent employment of other measures, minor or serious. Electrolysis was best adapted for the treatment of annular strictures rather limited in length. Having ascertained the situation of the stricture, the tip or exposed metal bulb of an electrode ought, if possible, to be lodged within it ; or, if this was impracticable, the tip must be in close contact with the anterior face of the stricture. Then a small galvanic battery was connected by its negative pole with the urethral electrode, while the positive might be attached either to a moist sponge electrode, or, better still, to a thin metal plate covered with moistened chamois-leather. The positive electrode would be advantageously applied either to the patient's perinæum, or against the inner side of one thigh. As to the strength of the current to be employed, the patient's own sensations would prove the best guide. The current should be perceived, but it ought not to be pushed to cause pain, nor should the surgeon attempt more than it was needful to effect at each sitting, using only mild currents, and manipulating the electrode with gentleness, and never pushing it through the stricture, as it accomplished more by being allowed to remain in the stricture than by being caused to quickly traverse it. The sittings might be repeated every ten days, if desired. Cauterizing would be pro-

duced when strong currents were employed ; but, with mild currents, the gradual breaking up of fibroid tissue was effected by a combination of chemical decomposition and vital absorption until but a thin lamella of cicatricial tissue remained to mark the seat of the stricture.

#### *INHALATIONS OF PURE CARBOLIC ACID IN WHOOPING-COUGH.*

Though the benefits derived from the inhalation of carbolie acid in the treatment of diphtheria and pertussis have long been well understood by practitioners, the exhibition of sufficiently strong solutions of carbolie acid have nevertheless been omitted in view of the great sensitiveness of children against this drug. As we learn from the *Deutsche Medicinische Wochenschrift*, 1886, xii. 21, DR. PICK, of Coblenz, has treated a number of children affected with whooping-cough by fixing an inhalation-mask in front of the mouth and nose and pouring into a piece of cotton in the interior of the mask, 15 to 20 drops of pure (liquefied) carbolie acid. The mask has to be worn, if possible, the entire day, but at least for six to eight hours, and the cotton is to be renewed three times daily. A careful investigation of the urine will give a timely warning of the danger of an intoxication.

In the cases treated by Pick the results were entirely satisfactory, so that he feels justified in recommending these inhalations as an efficient means to combat the affection.

#### *THE USES OF HOT WATER IN SOME OF THE CORNEAL AND CONJUNCTIVAL INFLAMMATIONS.*

The above is the title of a paper read by DR. B. E. FRYER, of Kansas City, before the recent meeting of the American Ophthalmological Society (*New York Med. Journ.*, August 14, 1886). In this plan of treatment water was used at as high a temperature as could be borne. After a few hours, a temperature of 140° F. could be tolerated. The water should not be cooler than this, but as much hotter as the patient could endure. A method of using it was by fomentation with a napkin dipped into the hot water and (not wrung out) applied to the closed eyelids. This was continued for half an hour at a time, and repeated every one, two, or three hours, day and night. It might also be applied by suspending a vessel above the patient and allowing the water to escape through a tube, thus

keeping up a continuous action. In some cases the temperature might be raised almost to the boiling point. During the intervals between the applications, a cloth wrung out of the hot water was allowed to remain over the eyes. In some cases of purulent ophthalmia the hot water might be thrown into the conjunctival sac. In purulent conjunctivitis this application cut short the attack more quickly and safely than the use of ice-cold water. In gonorrheal ophthalmia it quickly lessened the swelling and diminished the tendency to ulceration of the cornea. If ulceration had begun, it was less likely to progress, and the amount of cicatricial tissue was lessened. In these cases the author occasionally used instillations of sublimate solution or finely-powdered iodoform. In catarrhal and phlyctenular ophthalmia it was a good adjuvant. In acute and chronic keratitis it was useful. Its most marked effects were seen in cases of corneal ulcer. The small amount of opaque tissue left was astonishing. The pain and photophobia were also diminished.

DR. SAMUEL THEOBALD, of Baltimore, had not used hot water in purulent troubles, but in interstitial and specific keratitis its use had been beneficial, and he thought it favored absorption of the opacity.

#### THE RELATIVE VALUE OF VARIOUS DISINFECTING AGENTS.

The infection of a wound during an operation springs either from its contact with hands not freed from micro-organisms, instruments, sponges, etc., or from the entrance of bacteria from the non-sterile atmosphere of the operating-room. The former source of infection is by far the more important one.

In order to experimentally ascertain the relative value of the most popular disinfecting agents, DR. KÜMMEL, of Hamburg, brought sponges, instruments, and other utensils of the operating-room in contact with Koch's gelatin-plates, and noted the number of subsequently formed colonies after using the various modes of disinfection (*Archiv für Klin. Chirurgie*, 1886, xxxiii. 3, p. 531).

Kümmel noted very essential differences between the cases in which the disinfection had been preceded by washes with potassium soap and those in which this precaution had not been taken.

Instruments taken from a cupboard, in which they had remained for some time, but free from every visible soiling, could not be sterilized by an immersion into a five per

cent. solution of carbolic acid, lasting two minutes. A contact of ten minutes with the solution, however, sufficed to kill all germs.

Other antiseptic agents, such as the sublimate soap, gave still less favorable results. The one per cent. Hg soap did not produce any reliable sterilization in fifteen minutes.

On the other hand, knives used in the dissecting-room and exceedingly soiled were rendered almost completely sterile by simply washing them with water and potassium soap. Complete sterilization could invariably be looked for by an immersion into a five per cent. solution of carbolic acid after the preceding use of the potassium soap. The same held true of sponges: disinfection without the preceding use of the potassium soap was uncertain and required ample time, while following its use it was both reliable and quick. The hands presented greater difficulties to a complete sterilization than either knives or sponges. Potassium soap and a five per cent. solution of carbolic acid by far excelled, also a one per cent. sublimate solution.

Kümmel also endeavored to sterilize the air of a room before and during an operation, but, as could be expected, failed completely. A spray being in action for some time did not even diminish the number of germs in existence, and only after the apparatus had ceased to work, the colonies were noted to have somewhat decreased. Very good results were obtained by thoroughly washing the walls and all the furniture in the room.

#### CACUR, A KAFFIR EMETIC.

The extensive use of emetics in the treatment of disease by the Kaffirs of South Africa is well known by dwellers with or travellers among these races.

One of their most frequently-employed emetics is a green or yellowish-green fruit known as cacur, cacuo, or small bitter apple. The plan of administration pursued by the Kaffirs is to heat the fruit, squirt out the contents into their mouths, and swallow the material thus expelled. In a quarter of an hour or thereabouts emesis then occurs. Two of the pepoes are so administered in the case of an adult; one in the case of a child. The plant grows largely in gardens as a weed, especially where melons and pumpkins are cultivated. When ripe, it is quite yellow, but is used by the natives when green or greenish-yellow. The plant is obviously one of the *Cucurbitaceæ*, and has been pronounced by

Prof. Oliver to be the *Cucumis myriocarpus*. The plant produces fruit very abundantly,—subglobose pepoes, about the size of a large gooseberry, green when unripe, yellow when mature, and beset somewhat sparingly with short soft prickles. Each pepo weighs from 60 to 100 grains, and on section presents three parietal placentæ, with numerous seeds embedded in a soft viscid pulp, which becomes much more fluid when warmed,—possibly the object of the heating practised by the Kaffirs. The pulp has a faint cucumber-like odor, and is decidedly but not intensely bitter. The rind is soft, and can only be peeled off with considerable difficulty; it, too, is somewhat bitter, but much less so than the pulp. The testa of the seeds, which are exalbuminous, have a feebly-bitter taste; the seed otherwise is tasteless. The plant, apart from the pepoes, seems inactive.

MR. G. ARMSTRONG ATKINSON obtained a specimen for investigation, and publishes the results of his study in the *Edinburgh Medical Journal*, July, 1886.

To test its action he took, on an empty stomach, 20 grains of the fresh pulp, and in about half an hour felt somewhat nauseated, but was not sick. Four or five hours afterwards he had some griping pains, and two or three hours after this was slightly purged. To a large fasting dog he administered, bruised with water, a pepo weighing 69 grains. No sickness was produced, and the dog seemed generally unaffected. In about eight or nine hours very watery diarrhoea occurred, which lasted for well on to twenty-four hours, the evacuations being bilious-looking, and containing much mucus. Some days later two pepoes, weighing together 118 grains, were administered in a similar manner, and in twenty minutes very free emesis occurred, the dog vomiting several times, the last vomit containing a little blood. Considerable salivation was also produced at the same time. After the vomiting ceased the animal rapidly returned to its normal condition, and no purgation followed.

From these brief notes it will be seen that the action of the drug is that of an emetic and of a cholagogue purgative; purgative in non-emetic doses, and in doses sufficient to produce emesis causing purgation, if sufficient of the active principle has been retained. Its emetic action is probably local.

As to the chemistry of the plant, Mr. Atkinson had, unfortunately, not sufficient material to make a satisfactory examination; but, so far as he went, he could find no trace of

any alkaloid, the activity seeming to depend upon a bitter neutral principle, readily soluble in water, or in eighty per cent. alcohol.

#### ON CADAVERIC AND PHYSIOLOGICAL ALKALOIDS.

The assumption that Selmi was the first to prepare and investigate the cadaveric alkaloids or ptomaine group appears to be erroneous; at least ARMAND GAUTIER, of Paris, claims this priority for himself in his recent exhaustive treatise of this subject published in the *Bull. de l'Acad. de Mèd.*, 1886, vol. xv., Nos. 2, 3. Omitting the process of preparation of these ptomaines, or, as Gautier terms them, "bacteria alkaloids," we will briefly discuss their physiological and toxicological relations.

The ptomaines, as prepared by Gautier, belong chiefly to the pyridine and hydropyridine group, and represent oily, colorless fluids of a strongly alkaline reaction, which neutralize strong acids, and partially even abstract carbonic acid from the atmosphere. They also form crystallizable salts, are easily oxidized, and well capable to reduce metallic salts. Among these alkaloids parvolin, collidin, and hydrocollidin represent the principal products of bacterial decomposition.

As to the physiological effects of the ptomaines, Gautier quotes the conclusions arrived at by Gianetti and Corona, two Italian observers of note, as follows: "The cadaveric poisons are generally intensely poisonous, and cause in frogs dilatation of the pupils, followed by contraction, tetanic convulsions, with subsequent muscular relaxation, cardiac weakness, and total loss of the sensibility of the skin. Gautier himself instituted several experiments, with a certain base ( $C_6H_{11}N$ ), which he had found to be identical with hydrocollidin. He found that in birds the alkaloid caused at first paralysis of the lower part of the spinal cord, the pupils, however, remaining normal. After death the heart was found to be filled with blood and in its diastolic phase.

Discussing the forensic aspects of the alkaloids, Gautier does not believe in the possibility of mistaking them for purposely-administered vegetable alkaloids.

Alongside of these cadaveric poisons there is another group of alkaloids that claims our attention, viz., that found normally in the economy, at least under certain conditions. These alkaloids are known under the name of leucomaines, and have been known ever since

Liebig, in 1849, discovered kreatinine, which is the best-known representative of this group. Next Liebreich found kreatine in the normal urine in 1869; then Pouchet allantoine and carnine, 1880, likewise in the urine. Gautier himself investigated the gland secretions of poisonous snakes, and ascertained the presence of alkaloidal substances without finding, however, the active principle of the saliva to be of an alkaloidal nature. Even from human saliva Gautier prepared an alkaloid, which, applied to birds, caused stupefaction.

In his conclusive remarks, Gautier dwells on the constant appearance of hydrocollidin among the cadaveric poisons, and regards this alkaloid, as it were, as the product of transformation of the most energetic species of bacteria. The leucomaines—*i.e.*, the alkaloids generated during life—are somewhat less toxic in their effects than the ptomaines, and partially act as narcotics upon the central nervous system, and partially upon the intestinal tract. Gautier regards the origin of leucomaines as a process of oxidation taking place in the animal tissues after the manner observed in anaerobic bacteria. The accumulation of these products of tissue-change, due to their insufficient elimination through the skin, kidneys, and intestines, cause symptoms similar to those described above, which, in their entity, form an intoxication disease. The organism, on the other hand, resists this autoinfection by direct oxidation and elimination, and only if either of these physiological processes is interfered with the leucomainic intoxication sets in. Finally, Gautier remarks that he found—for example, in the snake-poison—alongside of these alkaloids other nitrogenous but non-crystallizable substances, which are much more poisonous, and which will form the subject of future investigations of his.

#### CONTINUOUS RECTAL ALIMENTATION— AN ARTIFICIAL STOMACH.

Thanks to the labors of Sir William Roberts, of Manchester, and others in the field of artificial alimentation, the practice of sustaining life by rectal feeding is becoming more encouraging. The difficulty, however, in intermittent administration lies in the fact that the enemata, though small, are apt to cause a desire for defæcation. It occurred to Dr. DUNCAN J. MCKENZIE (*Brit. Med. Journ.*, June 19, 1886) that we might imitate the process of nature more closely by the gradual passage of a fluid from an artificial cavity in which its digestion takes place into the rec-

tum for absorption. In this way the supply keeps pace with the absorption, and the belly is not loaded. The way in which he proceeds is as follows:

A piece of celluloid catheter (No. 5) is passed into the anus for about two inches; if passed too far, there is a risk of its being closed by the folds of gut. When once introduced, the sphincter closes upon it, and its presence is hardly felt by the patient; and the celluloid, rigid when introduced, becomes rather softer from the heat of the body. Previously to introduction, this piece of catheter is passed through a thick piece of india-rubber, perforated so as to grasp the catheter tightly. To the four corners of the india-rubber are attached tapes, which are tied, two in front and two behind, to a band round the loins. The india-rubber is passed close up to the anus, and the tapes are tied as tight as convenient. Over the outer end of the catheter is passed one end of a piece of fine india-rubber tubing, such as is used for babies' feeding-bottles. The piece of tubing should be about two yards long, and its other end slipped over a metal tube let in close to the bottom of a moderately tall narrow vessel, made of tin or other material, and capable of holding a pint of fluid. To increase steadiness, the bottom is leaded on the outside. The only other apparatus required are a milk-strainer to fit the mouth of the vessel, a table about the same height as the bed on which the patient lies, a few small boxes, or some suitable support by which the elevation can be varied, and an ordinary tea-cosy.

A pint of milk is warmed to a temperature suitable for pancreatic digestion; a little bicarbonate of sodium, and a proper quantity of some preparation of pancreas is added, and it is allowed to stand in a moderately-warm place for half an hour. It is then passed through the strainer into the vessel mentioned above. Dr. McKenzie finds that, after standing half an hour, the milk leaves little or no curd upon the strainer, and, when strained, readily passes through the tubes. If the curdling of the milk, by the pancreatic extract, give trouble, it may be prevented by previously adding one-fourth of its bulk of water to the milk (Roberts).

The milk, having been put into the vessel, which acts as the artificial stomach, it is raised from two to two and one-half feet above the level of the patient's bed, the height being altered according to the rapidity with which the milk runs through the tube. The vessel is then covered with the cosy to

keep it warm, and, if necessary, a heated plate may be put under it at intervals. The pint of milk should run into the rectum in about three hours, which time fairly corresponds to the average digestion-period of pancreatized milk. If a desire for defæcation be felt, the flow should be made slower, or the apparatus entirely removed for a time.

When the milk has all run out, the apparatus is removed, some clean water passed through the tubes, and the patient allowed to rest for a time before reintroduction.

In this way, a patient of Dr. McKenzie's, suffering from cancer of the stomach, in whom the colon was obstructed at the junction of the transverse with the descending portions, received an average of three pints of milk per day for a month, with an average daily evacuation of about a pint, consisting chiefly of curd; his nutrition was fairly kept up until vomiting of blood, mucus, and fæcal matter became excessive; and, after death, the whole descending colon was found well nourished and containing condensed milk. His evacuations generally took place from two to eight or nine hours after milk had been administered, care being taken not to give any when the rectum felt irritable.

#### FILEHNE'S LATEST OBSERVATIONS ON CAFFEINE AND ALLIED SUB- STANCES.

PROF. W. FILEHNE, of Erlangen, has instituted another series of experiments with the caffeine group, and communicated his valuable results to the *Archiv für Anatomie und Physiologie (Physiol. Abtheil.)*, 1886, Nos. 1, 2, from which we have prepared the following condensation:

##### I. CAFFEINE.

Caffeine produces, according to the majority of authors, when given to frogs in a sufficiently large dose, muscular rigidity and even tetanus. Schmiedeberg, however, claims that these effects can only be obtained in the rana temporaria, and that in the rana esculenta the convulsive phenomena originating from the central nervous system predominate. On the second or third day of the experiment these differences equalize each other, the former species of frogs showing a heightened reflex irritability, and the latter a certain muscular rigidity.

In no other animal besides the frog does caffeine produce such prompt and complete

rigidity, though Johannsen and Binz speak of muscular stiffness caused by the drug in cats and dogs. Filehne has, by his carefully-conducted experiments, disproven the claims of Schmiedeberg, as stated above. 7 mgrms. of caffeine injected under the skin of an esculenta weighing about 20 grms., sufficed to generate a reflex hyperirritability with irradiation of reflexes; 12 mgrms. caused very soon a lasting tetanus.—0.05 to 0.15 gm. of caffeine introduced into the stomach produced a muscular rigidity, appearing very promptly and rapidly reaching a maximum. This shows that, provided larger doses are used in experimenting, there is but a difference of degree and not of principle in the behavior of the two species of frogs under the influence of caffeine.

##### II. THEOBROMINE.

The observations made heretofore on theobromine are very scanty. According to Mitscherlich (*Der Cacao und die Chocolate*, Berlin, 1859, p. 88) the drug has qualitatively an action similar to that of caffeine; 0.06 gm. of it suffice to kill a frog. Filehne experimenting with theobromine obtained by the hypodermic injection of 7 mgrms. in frogs no other effects besides a reduction of the motor power. Using after four hours 5 more mgrms., he noted the gradual decrease of voluntary motions and reflex action until death set in through central paralysis after eighteen hours. Quite different effects, however, were obtained by the employment of large doses (15–30–50 mgrms.) from the beginning. Fifteen minutes after administration of the drug the entire muscular apparatus of the animal assumed a rapidly-deepening rigidity, from which the cardiac muscle alone is exempted. This rigidity takes place just the same in muscles, the nerve of which has been cut, and also in curarized animals, but not in parts in which the artery has been tied. Shortly before appearance of the rigidity reflex sensibility is distinctly lowered.

##### III. XANTINE.

The spinal paralysis and muscular rigidity, as produced by both caffeine and theobromine, can likewise and to a still greater extent be provoked by xantine. If the iliac artery is tied, we obtain a gradual decrease of the voluntary and reflex motions of the corresponding extremity without any preceding increase of reflex sensibility. It is noteworthy that while even after larger doses of caffeine and theobromine the heart-muscle remains intact, this organ under the influence

of xantine presents early signs of rigidity, though it continues to beat.

#### DERIVATIVES OF CAFFEINE.

(a) *Hydroxy-Caffeine*.—This substance injected into the lymph-spaces causes, even in a quantity of 100 mgrms., no obvious effects. Filehne attributes this to the fact of the drug being readily decomposed in the organism; doses of 0.2 grm., however, produced caffeine-like symptoms.

(b) *Diethoxy-hydroxy-Caffeine*.—This derivative showed itself also to be inert in the frog, and very probably for the reason given above.

(c) *Ethoxy-Caffeine*.—The addition of the ethyl group lends to this chemical a peculiar narcotic influence upon the brain and spinal cord. It causes stupefaction and paralysis without affecting the circulation or (to any great extent) the motor apparatus. In rabbits the drug causes sopor and actual sleep if injected into the stomach in a dose of 0.5 grm. In man the drug causes no effects in a dose of 0.2 grm.; after gifts of 0.3 to 0.5 grm. the arterial tension is raised (the pulse increasing two to six beats per minute), the face reddens, sweating and a soporous state sets in. Doses of 0.5 to 0.75 grm. produce severe headache and coma. Gifts of 0.1 to 0.5 grm. cause a somewhat sounder sleep than normally present; still larger doses, however, disturb the sleep. Filehne advocates the trial of this drug in cases of megrim.

#### PRODUCTS OF DECOMPOSITION OF CAFFEINE.

(a) Caffeidine shows in doses of 100 mgrms. a slight caffeine-like action. (Stricker.)

(b) Caffuric acid causes in the same dose a temporary increase of the reflex excitability and a certain muscular relaxation.

(c) Hypo-caffeine is totally inert in doses of 50 mgrms.; in larger doses a slight hyperæsthesia results.

(d) Caffoline is totally inert.

#### SUBSTANCES ALLIED TO THE XANTHINE-CAFFEINE GROUP.

(a) Guanine is in doses of 100 mgrms. and more is inert in frogs.

(b) Uric acid (an oxy-xantine) is likewise inert.

#### SARKINE.

Though, according to Fischer and Kossel (*Zeitschrift für physiologische Chemie*, vol. vi. p. 428), the chemical relationship of sarkine to the xantine group is of a doubtful nature, Filehne examined its physiological action, nevertheless, in connection with the

above researches. Doses of 15 to 100 mgrms. cause an increased reflex sensibility and reflex irradiation, with spontaneous paroxysmal cramps becoming ultimately tetanic in nature. Death finally ensued under symptoms of extreme muscular rigidity.

#### CARBOLIC ACID IN THE TREATMENT OF WHOOPING-COUGH.

DR. C. W. SUCKLING writes to the *British Med. Journal*, July 24, 1886, that he has used the glycerin of carbollic acid with great success among his out-patients at the Children's Hospital in the treatment of whooping-cough. He had previously used almost every other drug in different cases, but never with any very satisfactory results. He states that he has notes of twenty-three cases treated with glycerin of carbollic acid.

Half a minim in peppermint-water is sufficient for a child a year old, the dose increasing with the age. In twenty cases, relief was quickly given; the general condition of the patients was at once improved, and the number and severity of the paroxysms of coughing diminished. None of these cases attended more than a fortnight, while the usual length of attendance is certainly twice as long. In three cases, the carbollic acid failed to give relief. There was no doubt as to the nature of the illness in these cases, for in all the characteristic cough was heard, or ulceration of the frænum present.

Dr. Suckling has observed ulceration of the frænum to be present in fifty per cent. of cases of whooping-cough, and he believes that its presence is pathognomic of the disease. He also believes carbollic acid almost deserves to be called a specific for pertussis.

#### THE PHYSIOLOGICAL AND THERAPEUTIC PROPERTIES OF ETHOXY-CAFFEINE AND OTHER DERIVATIVES OF CAFFEINE.

DUJARDIN-BEAUMETZ, convincing himself of the correctness of Filehne's observations on the derivatives of caffeine, tried ethoxy-caffeine in a number of affections marked by cephalalgia (*vide Bull. de Thérap.*, vol. cx., March 30, 1886). In order to render this drug soluble in water, and at the same time to obviate the dyspeptic symptoms easily caused by it, Dujardin-Beaumetz recommends the following mixture:

R Ethoxy-caffeine,  
Sodii salicyl., aa gr. iii;  
Cocain. mur., gr. iss;  
Aque tiliæ, fʒii;  
Syr. simpl., fʒi. M.  
S.—Take at once.

The results obtained with this drug in megrim were highly satisfactory. In one case the drug was given in a dose of about 1 grain at the height of a paroxysmal pain in the head, with the effect of wholly removing the pain in two hours. In four other cases the pain was abated in less than one hour. Dujardin-Beaumetz advises to give no larger doses than 3 grains, since 7 grains can produce gastric cramps, nausea, and even cerebral disturbances. In cases of prosopalgia the drug proved likewise to bring relief and cause sleep.

These and similar observations have led Dujardin-Beaumetz to assume that ethoxy-caffeine prevents the therapeutic and physiological effects of caffeine in a modified manner, and that it owns a pronounced sedative or narcotic action, allowing of its advantageous substitution for caffeine in cases of megrim.

#### THE INFLUENCE OF PURE TEREBENE ON FERMENTATION.

In a lecture recently delivered at the Westminster Hospital, DR. MURRELL referred to the power exerted by pure terebene in arresting fermentation, and gave the details of some experiments which he had made. He took two beakers of the same size and shape, and, in each of them, placed two hundred and sixty-five cubic centimetres of water and a little hay. To one of them he added half a cubic centimetre of pure terebene. Both beakers were covered with glass plates, and placed in a warm chamber, at 36° C. (96.8° Fahr.). Two days later the test-beaker was examined, and the fluid was found to be swarming with moving particles, so minute that they could with difficulty be seen with a Zeiss D. The other beaker smelt strongly of the pure terebene, but nothing moving could be detected when examined with the same lens. On the ninth day from the commencement of the observation the hay-infusion was turbid; a film had formed on the surface, and the fluid was distinctly offensive. Under the Zeiss D numerous monads were seen, with large numbers of moving organisms. The other beaker was clear; there was no film on the surface; the slight sweet smell of pure terebene was still perceptible, and moving organisms and

monads were absent. On the eleventh day the temperature of the warm chamber was somewhat higher, having risen to 40° C. (104° Fahr.). The specimens being again examined under the Zeiss and a Ross's one-eighth power, the field of number 1 was found to be covered with moving organisms, but in number 2 nothing was to be seen on most careful examination. The test was a rough one, but it is clear that a two per cent. solution of pure terebene will arrest fermentation in a hay-infusion. On a subsequent occasion the experiment was repeated with 1 part in 1000 of pure terebene, the infusion being kept this time at a temperature of 20° C. (68° Fahr.). In fifty-one hours the test-solution, examined with a one-twelfth Ross's objective, was found to contain hay-bacilli in large quantities in motion, also numerous paramœcia. The solution containing terebene (number 2) was not absolutely free from moving organisms, but they were fewer and less developed, and no paramœcia were found. At the expiration of seventy-five hours number 1 was seen to be swarming with paramœcia and hay-bacilli breaking up into spores; number 2 contained only a few moving organisms, and no paramœcia. Two days later number 2 was swarming with paramœcia, whilst they had all disappeared from number 1. The influence of pure terebene on paramœcia was demonstrated in another way. A specimen of hay-infusion swarming with paramœcia was put under the microscope and examined with Ross's one-twelfth inch. Several large specimens being under observation, a drop of pure terebene was placed at the edge of the cover-glass, and drawn through with blotting-paper. The paramœcia were at first but little affected, but after a time their movements almost ceased, although their cilia could still be seen languidly beating. A drop of water was then drawn through, and almost immediately the paramœcia became as active in their movements as ever.

Pure terebene was found to have the power of arresting or preventing the fermentation of yeast. Two small bottles, of identical size and shape, were filled with a mixture of saccharine urine and yeast. To one bottle was added pure terebene, in the proportion of 1 in 450. The bottles were inverted in the ordinary way, in a flat vessel containing water, and were placed in the warm chamber. In forty-eight hours fermentation had taken place in one bottle, and all the fluid had been driven out, while the bottle to which terebene had been added remained full. On the third day

a few small bubbles of gas appeared in it, and on the seventeenth day it contained only about one-fourth of gas. The effect of pure terebene in this experiment was very marked. On another occasion two bottles were taken, each holding six and a half ounces. In each was placed half an ounce of cane-sugar syrup mixed with a little yeast. One was filled with water; the other with water containing 1 in 1000 of pure terebene; and both were inverted in shallow dishes containing water, and placed in a warm chamber. The bottles were observed day by day for six days, and the carbonic acid gas was found to accumulate twice as quickly in the former as in the latter. On another occasion two specimens were treated in a similar manner, and at the expiration of fifty-one hours both were examined microscopically. There was not much difference in the character of the torulæ, but those in the bottle containing terebene were less developed.

Pure terebene undoubtedly exerts an influence on lactic acid fermentation. Two beakers were taken, each containing two hundred and fifty cubic centimetres of fresh milk. To one of them was added five cubic centimetres of pure terebene, and both were placed in the warm chamber, at a temperature of 42° C. (107.6° Fahr.). At the expiration of twenty hours they were examined. The milk in one was found to be curdled, and strongly acid. That in the beaker containing terebene had a slight film on the surface, but was quite fresh, and was neutral in reaction. It was sweet and pleasant to the taste, except for the smell of pure terebene. The greater part of the pure terebene was found floating at the top. Twenty-three hours later this milk was curdled, and had a strong acid reaction.

Dr. Murrell stated that these observations were made in the Physiological Laboratory of the Westminster Hospital, in December, 1880, and led to a trial of the drug in cases of irregular fermentation in the stomach,—acidity, flatulence, etc.; and its subsequent introduction as a remedy for winter-cough.—*Brit. Med. Journ.*, July 24, 1886.

#### THE ALKALOIDS OF JABORANDI-LEAVES.

PROF. HARNACK, of Halle, and H. MEYER, in some previous publication (*Annalen der Chemie*, vol. cciv., p. 67), pointed out that pilocarpine could easily be changed into jaborine, a substance acting like atropine, and

Merck even claimed that jaborine was always present in minute quantities in the commercial pilocarpine. And still another alkaloid besides pilocarpine and jaborine has recently been obtained by Meyer, which he termed pilocarpidine, and described in the *Archiv für experimentelle Pathologie*, 1886, vol. xx., Nos. 5, 6. Omitting the chemical properties of the new alkaloid, which approximate those of pilocarpine closely, we beg to briefly review its principal physiological features.

The action of pilocarpidine is essentially identical with that of pilocarpine, only less pronounced. In a cat 7 weeks old which received 0.01 grm. of pilocarpidine hypodermically the drug induced a state of intoxication, which would have been fatal unless speedily counteracted by atropine. Among the more prominent symptoms of the poisoning by pilocarpidine Meyer mentions increased perspiration and lachrymation, besides diarrhoea, vomiting, and dyspnoea. In rabbits pilocarpidine causes likewise salivation and diarrhoea, but does not, even in doses of 0.2 grm. (3 grains), susceptible influence the respiratory and cardiac functions. While 0.1 grm. of pilocarpine (1½ grains) produces in a rabbit a profound intoxication and death, Meyer observed, after the subcutaneous employment of 0.5 grm. (7 grains) of pilocarpidine, no materially morbid symptoms; even 0.3 grm. (4½ grains) introduced directly into the circulation caused no intoxication. It is probable that the innocuousness of the drug results from its rapid decomposition in the animal organism. In frogs pilocarpidine showed likewise a much weaker action than pilocarpine. Jaboridine (an alkaloid into which pilocarpidine is easily changed) has hitherto, by Meyer, been tested exclusively on the frog's heart, and was found to closely resemble in its physiological properties those of jaborine and atropine, as intimated above.

#### THE ALTERNATIVES OF CRANIOTOMY.

At the meeting of the British Medical Association, recently held at Brighton, England, DR. BARNES read a paper with the above title before the Obstetrical Section, of which the following is a summary (*Lancet*, August 14, 1886):

1. The legitimate aspiration and the tendency of science is to eliminate craniotomy on the living and viable child from obstetric

practice. 2. The advance of hygienic rule, the improvements, the forceps, in turning, in the induction of labor, and in obstetrics generally, have materially curtailed the field within which craniotomy can be justifiably applied. The extension of the axis-traction curve to the forceps will, he believes, still further curtail the resort to craniotomy. 3. In the most extreme degrees of pelvic distortion, where delivery *per vias naturales* can only be effected by the best appliances and the highest skill, and with appreciable risk to the mother, Porro's operation is the legitimate alternative for craniotomy, if the opportunity of inducing abortion be gone by. 4. In less advanced degrees of pelvic contraction, but still incompatible with the delivery of a living child *per vias naturales*, the opportunity of inducing abortion having gone by, the Cæsarean section may be a legitimate alternative of craniotomy. This is the most debatable point. 5. In the minor degrees of contraction, say from three inches to three and a half inches, the opportunity for inducing premature labor having gone by, the far greater safety to the mother obtained by craniotomy makes this the proper course to adopt; at least, until it can be shown that the Cæsarean section is so improved as to be equally safe to the mother. The mother's right to be rescued stands before that of the child. 6. In other emergencies than deformity, as in obstructed labor from ovarian tumors, the alternative to craniotomy, if possible, is to remove the tumor. 7. In cases of immovable tumors, Porro's operation is the proper alternative. 8. In ruptures of the uterus, the child being delivered or not, Porro's operation is the proper alternative. The interests of mother and child coincide. 9. In cases of disease or tumors of the uterus, Porro's operation will generally be the proper alternative. 10. In atresia of the cervix or vagina, craniotomy or Cæsarean section may be necessary, but incisions and dilatation may more frequently be the proper alternative. 11. When obstruction is due to hydrocephalus, or dropsy in the child, embryotomy or tapping is indicated. 12. When the child is dead, embryotomy is indicated, and decollation when turning is hazardous from impactions of the child. 13. In convulsions and hemorrhages, the proper alternatives for craniotomy are found in the more scientific methods of concluding labors under these complications. Lastly. But the dream of Tyler Smith, the abolition of craniotomy, will be fully realized only when hygiene shall have triumphed over disease and deformity.

#### NEW FACTS ABOUT COCAINE.

DUJARDIN-BEAUMETZ communicates to the *Bull. de Thérap.*, vol. cix., No. 12, p. 529, a number of interesting data concerning cocaine, partly of an historical and partly of a therapeutic character, which we will present to our readers *en résumé*.

According to our author the anæsthetic action of cocaine has been called attention to as early as 1868 by Moreno y Meris (*Sur la Cocaine, Thèse de Paris*, 1868), and its analgesic virtues have been utilized in affections of the pharynx and larynx as early as 1877 by Saglia, Cazal, and Gougenheim, as can be seen from the *Bulletin de Thérapeutique*, 1882, p. 53. It is probable, however, that not the alkaloid cocaine, but the coca-leaves, or an extract prepared from them, was used by these physicians.

Cocaine appears to have an action just opposite to that of curare, and applied locally anæsthetizes not only mucous membranes, but also the skin. If 0.02 grm. ( $\frac{1}{3}$  grain) of a two per cent. solution of cocaine is injected into the forearm, the skin loses its susceptibility over the point of injection and neighboring area for at least twenty to thirty minutes. Still, such injections are mostly attended by constitutional disturbances of no light nature. Drs. Bardet and Meyer, assistants of Dujardin-Beaumetz, anæsthetizing for the sake of an experiment their own skin, observed on themselves half an hour after the injection a considerable dilatation of the pupils and comatose symptoms. One of them fell in a state of vertigo, marked by pallor of the face and extreme weakness of cardiac action. These symptoms, moreover, recurred at every attempt to leave the horizontal position. In patients, Dujardin-Beaumetz observed analogous phenomena. A woman who, for the purpose of a painless dilatation of the anus, had received a hypodermic injection of cocaine into the perineum, was seized by vertigo, nausea, and a cramp-like working of the nostrils. Another patient experienced similar sensations, and in addition to them a feeling of growing lighter and flying away. All these evidences of intoxication had resulted after hypodermic doses of 0.01 to 0.02 grm. ( $\frac{1}{6}$  to  $\frac{1}{3}$  grain), doses which had been never exceeded. The fact that the stated symptoms occurred only in the erect position seems to suggest their relation to a state of cerebral anæmia caused by cocaine, an assumption which is strengthened by the observation that the mentioned phenomena did not occur in robust persons, and

were singularly pronounced in anæmic individuals.

According to the testimony of Grasset and Nègre, cocaine causes in animals cramps of a clonic nature. In monkeys 0.06 grm. (1 grain) were required to obtain this effect. The influence of the drug upon the animal temperature is manifest, though different according to the species of animals experimented upon. In a dog the temperature is raised, in the monkey lowered. Applied to the exposed blood-vessels of a frog, cocaine produces at first a distinct dilatation, and later a strong contraction, as observed by Rigolet, with a one per cent. solution. To obtain direct evidences of poisoning somewhat larger doses are required. Rigolet gave to a dog weighing eighteen kilogrammes 0.43 grms. (6 grains) of hydrochlorate of cocaine by intravenous injection without any detriment, and Bignon (of Lima) has figured out that the Indians take with impunity as much as 0.4 grm. (6 grains) of cocaine by the chewing of coca-leaves.

According to this observer cocaine is also soluble in vaseline, though he never saw any anæsthetic effects resulting from the rubbing in of this vaseline or of other solutions of cocaine into the skin, provided the epidermis was intact. To obtain anæsthesia cocaine is to be applied upon the denuded cutis or subcutaneously. In the former application the action of cocaine is very prompt, and can be advantageously employed to obviate the intense pains following upon severe burns and other accidents. Dujardin-Beaumetz recommends the exhibition of cocaine subcutaneously in all those cases in which a painful operative section of the cutis is necessitated. He has successfully resorted to the cocaine injection in cases of pleurotomy, in the opening of abscesses, tracheotomy, and the extirpation of a lupous neoplasm. It is best to inject about ten minutes previous to the operation, the patient being in a horizontal position. In operations for phimosis the cocaine injections are contraindicated on account of the resulting œdema.

Locally, solutions of cocaine are to be warmly recommended in almost all painful affections of the larynx and pharynx, in tubercular subjects a few minutes before meals to facilitate the often painful swallowing, before introduction of the œsophageal bougie to check the attempts at vomiting, and finally interstitial injections in the anal region for a painless dilatation of the sphincter. Likewise are the suppositories of cocaine indicated in

painful hemorrhoids and in vaginismus. Dujardin-Beaumetz has also employed cocaine internally, and pronounces its analgesic virtues in all painful and cramp-like conditions of the stomach truly marvellous, far surpassing the services rendered by opium.

In this connection our readers will recall that cocaine has also been recommended in singultus (by Compardon) and in whooping-cough (by Prior), but that Henoch never saw any beneficial results of its application in the latter affection.

#### THE TREATMENT OF NEPHRITIS.

According to the Paris correspondent of the *Lancet* (July 24, 1886), it is admitted in practice that nephritis in patients suffering from scarlet fever is not always in relation to the gravity of the eruptive disease. Prof. Jaccoud, following the example of Dr. Musatti, who established the fact that milk diet, instituted at the commencement of the malady, is the best remedy to prevent renal complications, employed the same treatment with great success. According to certain authors, renal albuminuria resulting from scarlet fever is very prevalent in some epidemics, and the number of cases so affected has been known to mount up to fifty per cent.,—that is, including both slight and grave cases; but Prof. Jaccoud, since adopting this method, has never had a single case of renal albuminuria. According to him, the real prophylactic treatment of this complication consists in the administration of milk from the first day of the malady, without waiting for the appearance of albumen in the urine. Milk alone should be given, both as food and medicine,—three litres per day if possible. Dr. Musatti condemns the use of the cold bath in scarlet fever, not only on account of the difficulties attending this mode of treatment, but also from the collapse and other complications that may be produced.

#### ANÆSTHESIA IN CONFINEMENT.

The questions whether or not anæsthesia is a desirable adjuvant of parturition, and what anæsthetics can claim the preference, will apparently never disappear from the store of professional discussions. Seemingly answered, settled and done away with, the subject is certain to loom up again after definite intervals.

In the Berlin gynæcological clinics (under

the superintendence of Schröder), Dr. E. Cohn instituted recently comparative trials with various anæsthetic agents, the result of which we find represented in *Schmidt's Jahrbücher* of June 1, 1886, p. 48. In Berlin the chloroform narcosis is the usual one, hence it was deemed only requisite to try monoxide of nitrogen and bromide of ethyl. We condense here the main conclusions arrived at by the experimenter.

The monoxide of nitrogen was mixed with oxygen in a proportion of two hundred volumes of the former to fifty volumes of the latter, and was administered from a gasometer through a mouth-piece covering the mouth and nose closely. Cohn could verify in general Döderlein's observations made with this gaseous mixture in labor, as set forth in the *Archiv für Gynæcology*, vol. xvii., No. 1. The heart was not influenced in any way by this gas, while the frequency of the respiratory act was distinctly raised by it, an observation directly opposed to that of Döderlein. A state of actual excitation was observed only in three cases out of twenty. Usually the confined women grew quiet after a few inhalations of the gas, answered correctly to all questions, and were well able to strain without having the consciousness of pain. On awaking after removal of the mask, the women never knew what had happened to them. In spite of the on the whole favorable results obtained with this anæsthetic, Cohn hesitates to recommend it for gynæcological practice on account of its being too unhandy to use, and besides of being too expensive, a single narcosis costing ten to twelve marks (two and a half to three dollars).

Cohn also took pains to ascertain the merits of bromide of ethyl, recommended three years ago for gynæcological purposes by Häckermann. According to Cohn's testimony, this anæsthetic does not unfavorably influence the straining process, removes pain, and leaves circulation and respiration wholly intact. There is one inconvenience, however, connected with this gas, viz., its garlic odor, which, after the elimination of the gas from the lungs of the woman, grows a source of discomfort to herself, her attendants, and possibly also to the child.

As to chloroform, it is well known that this gas exerts also a decidedly favorable impress upon parturition, removing the sensation of pain without lessening the straining power of the woman, provided no complete anæsthesia is induced. Chloroform has besides never been known to have produced any detri-

mental after-effects to the confined woman. Asphyctic conditions are exceedingly rare, provided the drug used be pure and no cardiac or pneumonic trouble present in the woman. The only objectionable feature in chloroform is that its action, especially in a prolonged narcosis, also affects the child. But as a prolonged narcosis is rather an exceptional requisite in confinement, the intimated objection of this anæsthetic is of little consideration. The general conclusion arrived at by Cohn from his comparative trials with various anæsthetic agents in confinement is that chloroform is the most eligible drug, and bromide of ethyl a valuable substitute for it.

#### EARLY OPERATIVE TREATMENT OF MORBUS COXÆ.

The April Bulletin of the Royal Academy of Medicine of Rome reports the presentation, by Dr. P. Postemski, of three boys with hip-disease. Two cases had been treated by the expectant method,—counter-irritation and extension, douching and immobility. Abscesses and sinuses formed, and recovery, with considerable deformity, only occurred after the treatment had been persisted in,—in one case for two, in the other for four years. In the third case early excision of the head of the femur was followed by rapid recovery. The operation was performed through a semi-lunar incision behind the great trochanter. The joint contained purulent serum, and was the seat of fungus synovitis. Only a few erosions were visible on the head of the bone. After removing it, the neck of the femur was rounded and refitted into the acetabulum, previously cleaned out by scraping. Drainage, union by interrupted suture, extension, and sublimate dressings were not disturbed for twenty-nine days, when union by first intention was ascertained. All the dressings were removed on the thirty-fifth day. At the end of eight weeks the patient was able to walk on crutches, and he could dispense with them when presented to the Academy. The case is unquestionably one of deep interest, but its progress at a later stage must be noted before a correct judgment can be formed. Assuming the issue to be entirely favorable, the advice to excise the head of the bone in the early stage of hip-disease raises grave questions. Granted that the danger of the operation is much less in children than in adults, and that the proportion of recoveries is largest when excision is practised before the joint is completely disorganized, two

results of experience are specially noteworthy. A large proportion of hip-joint patients do well under appropriate constitutional and local treatment; and excision of the hip is an operation involving risk to life, without the certainty of a strong and useful limb.—*Lancet*, July 24, 1886.

#### NEURALGIA OF THE PUDIC NERVE.

PROFESSOR ADAMKIEWICZ mentions in the Polish journal *Medycyna* a somewhat rare case of neuralgia affecting the pudic nerve. The neuralgias of the ovary and uterus in women and of the seminal ducts in men are, he says, usually described as neuralgiæ pudendo-hæmorrhoidales, but they have not been well worked out. The present case is interesting because the nerve affected arises from the pelvic plexus. Three years ago the patient began to suffer two months after her second confinement with painful spasm of the urethra whenever she attempted to micturate; sometimes, indeed, this spasm prevented her from voiding her urine. Afterwards the pain spread to the vesical region and became more and more frequent, so that at last the woman was scarcely ever free from it. Every movement of the body and any irritation or excitement increased it, and induced a desire to micturate. Morphine and absolute rest in bed produced some alleviation only. A painful spot was found where the gluteus maximus crosses the tuberosity of the ischium, and another on the inner surface of the ascending ramus of the ischium. The treatment adopted was electrical, the anode of a constant current battery being placed between the tuberosity and the spine of the ischium, and the cathode on the sacrum. After daily applications of a few minutes' duration for three months the patient was completely cured.—*Lancet*, July 24, 1886.

#### PROPRIETARY MEDICINES.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I have a few words to say about proprietary medicines, a question of vital importance to every physician,—a question which has already been discussed in the GAZETTE from the ethical and legal point of view, but whose business relation with physicians, the question of dollars and cents, does not seem to have been appreciated. For the

last ten to twenty years the whole horde of so-called manufacturing chemists and pharmacists have been putting upon the markets various sorts of proprietary nostrums. At first there were many of us that looked upon it as a commendable business, but now there are many of us who can plainly see that, from a business point of view, it is the worst enemy that the profession has to contend with. When these remedies were first originated the owners or proprietors depended upon the profession to introduce them, or at least they pretended so to do. But they were not satisfied with the legitimate demand that was thus produced, but then commenced advertising in the daily and weekly press, and thus brought themselves down to the position occupied by such men as vendors of "cure-alls." You can scarcely pick up a paper to-day without the first thing you see is *Tongaline*, or some other similar substance, in blazing type, lauded to the skies as a positive cure of about all the diseases known of nervous origin. You see attached the testimonials of popes, clergymen, and bishops, and you usually find the regulation lie attached,—i.e., that the poor unfortunate had been the rounds of all the doctors, and had no benefit until he got *Tongaline*, etc. Now I don't hesitate to say that the companies that manufacture and advertise such trash are working against the physician direct, and also that they are not honest, and their remedies should be boycotted by the profession. The remedy mentioned is illustrative of a great many others on the market equally objectionable.

I think it is time that the profession was roused upon this question. We must protect ourselves, or sooner or later the load will be too heavy for us to stand up under. There is no doubt in the world but what the science of medicine is making gigantic strides, as far as the acquisition of knowledge is concerned; but, on the other hand, contrary to justice and right, our worth and benefit to society is not acknowledged by the masses as it should be, and I lay the blame at the door of these quack nostrums, whose advertisements are to be seen in almost every paper. Coming out in plain words, and giving the therapy of their remedies, telling the names of the diseases for which they are to be used, thus placing the remedies directly in the hands of the laity.

It is a fact that the larger per cent. of the cases we are called to see nowadays here in this country are critical cases, made so by the patient depending on these proprietary reme-

dies and simply sending for the doctor as a last resort. You take the ordinary physician, and the practice that he desires most is just the kind that is taken away from him by these quack nostrums. For my part I am getting tired of it, and I want the agitation of this question to commence and be kept up until something is accomplished.

I have nothing to say against a remedy whose correct formula is on each bottle; this plan will insure a pure and cheap article, since with the removal of secrecy the incentive to fraud is removed. We have to go to work and sustain ourselves. We have the intelligence, the influence, and the right on our side, and we cannot afford to ignore this question. If we do not defend ourselves the proprietary medicine-man and druggist will completely do away with our business. Why here last year I told a druggist to get some bromo-caffeine, which I prescribed for a lady's headache; it cured her and I got fifty cents for the prescription. Since that time the remedy has been sold indiscriminately by the druggist. He has even sold it in the original package without destroying the label, and it is nothing for the people to go to the druggist first when they want medicine. Bromo-caffeine is all right, but it was a decidedly losing investment for me when I ordered it. Now let all physicians who have their best interests at heart join in and use their influence against any manufacturer who stoops to quackery and charlatanism by advertising his or their remedies outside of proper channels, or who keeps secret the formula. Never prescribe any nostrum whose label does not contain the correct working formula. We can influence legislation, we can work among our patrons, and in our daily intercourse with men we can start the ball rolling; in fact, we can in the next ten years make ourselves heard and felt all over the land.

Yours respectfully,

J. Z. SCOTT, M.D.

SCANDIA, KANSAS, July 16, 1886.

#### TREATMENT OF IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I have read with more than ordinary interest the reports from different sources on ivy-poisoning. Not only for information gained, but from the fact that I have had my share in the experimental treatment of the trouble.

As has been stated, cases would present themselves so badly poisoned as to make the

features entirely beyond recognition, and often the whole body the same way, with all the accompanying discomforts. I tried the whole list of prescribed remedies with but partial or no relief.

One day a patient came in suffering terribly on whom I had been experimenting, saying I must certainly do something for his relief, as he could stand it no longer. There was a bottle of bromine on my table that I had been using as caustic. I determined to try a mild preparation of it in this case, as it might by its caustic action neutralize the poison. So I fixed up the following, with the result that in two days he was perfectly comfortable:

R Bromine, gtt. xxx;  
Vaseline, ℥iii;  
Glycerin, ℥ii;  
Cologne, q.s. to scent. M.

S.—Apply morning, noon, and night, first washing the poisoned part with salt water. Let the ointment remain one-half to one hour, then wash off with any fine soap.

I have used this time and again since, and no difference how bad the poison, always with the same result. It always stopped the trouble in two to four days.

J. W. LILLY, M.D.

TOLEDO, OHIO, August 21, 1886.

#### TREATMENT OF IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In the July number of the GAZETTE I note the inquiry of L. B. Parsell, M.D., of Closter, N. Y., relative to the treatment of ivy-poisoning. Having had a number of cases this present year, I found in seventeen cases that the following prescription acted almost as a specific, cutting short the spread of the poison and allaying the intense itching:

R Plumbi acetat., ℥ii;  
Bromo-chloral, ℥i;  
Aqua pura, q.s. ℥iv. M.

S.—Shake well, and apply three or four times a day, first washing parts well with warm water and Castile soap. The strength can be varied according to age of person and severity of poison.

Would be glad to hear through medium of GAZETTE the results of the same.

Respectfully,

M. A. HOOVER, M.D.

KEARNEY, NEB., August 19, 1886.

#### COCAINE IN DYSENTERY.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In the GAZETTE of July 15, Dr. R. L. Hinton gives his experience in the

use of cocaine, and calls the attention of the profession to its value in dysentery.

The *New York Medical Journal*, of April 24, 1886, contains the proceedings of the Clinical Society, of January 22, 1886, at which meeting I reported the good results I had had in dysentery treated by cocaine.

The *New York Medical Record*, of December 5, 1885, and February 20, 1886, gives short notices on the same subject.

In my lectures to the students of the Medical Department of the New York University, at the opening of the session of '85-'86, I taught the application of this new and important therapeutic agent in dysentery.

Yours respectfully,

JOSEPH E. WINTERS.

36 W. 32D ST., NEW YORK, August 3, 1886.

#### TREATMENT OF IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—On page 491 of the July number of THERAPEUTIC GAZETTE, Dr. L. B. Parsell, of Closter, N. Y., asks for a remedy that will cure the poison of rhus toxicodendron, to which I would like to reply through the columns of your valuable journal, not only for his benefit but for that of all others, by referring him to page 286, August number of THERAPEUTIC GAZETTE, 1882, where I have already answered this question. I have never, for about twenty-five years, prescribed anything for this rash except the cold infusion of red sassafras-root applied by wet cloths and the drinking three times a day, or *ad libitum*, the warm tea of the same. Never failed to cure the most aggravated cases in one to three days, without a single exception, and I have had cases come to me that had baffled other physicians. This is a simple remedy, cheap, and pleasant to the patient, and I wish every physician who has a case of this rash, and can procure the fresh root, would give it a trial.

R. L. HINTON, M.D.

PRESCOTT, ARK., NEVADA CO., August 4, 1886.

#### TREATMENT OF IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In your July number, Dr. Parsell asks for a remedy for the poison of ivy. In addition to the prescriptions from the *Journal of Cutaneous and Venereal Diseases*, which you quote, I would suggest a trial of *menthol*, a solution in ether or alcohol of one drachm to the ounce. Although I

have not used this drug in this particular affection, my experience with it in erythemas due to other causes has been so favorable that it would seem to merit trial in this (see page 51 of the current volume of the GAZETTE). And if Dr. Parsell would be kind enough, I would be glad to see his report in some future number of your journal.

Very truly yours,

SELWYN A. RUSSELL, M.D.

135 N. PEARL ST., ALBANY, N. Y.

#### THE TREATMENT OF IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I see in the July number of the GAZETTE an inquiry made by L. B. Parsell, M.D., of Closter, N. Y., asking for "a remedy for the poison of wild ivy."

I have been engaged in the practice of medicine in the West since 1852, and have treated a large number of cases of ivy-poisoning with satisfactory results, and I think the following formula will prove very nearly a "specific":

R Solanum dulc. (bittersweet), bark of root,  $\mathfrak{z}\text{i}$ ;  
Sambucus (elder), inner bark,  
Lobelia inf. (herb),  $\mathfrak{aa}$   $\mathfrak{z}\text{i}$ ;  
Lard (or vaseline),  $\mathfrak{z}\text{iv}$ . M.

Simmer over a slow fire for four hours. Strain, and apply freely to the parts affected.

If the case is a bad one, saturate a thin cloth with the salve, and keep the affected parts wholly covered with the cloth.

Yours,

B. C. PARKER, M.D.

WILBER, NEB., August 4, 1886.

#### TEST FOR NITRITES IN WATER.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In a recent number of the THERAPEUTIC GAZETTE there is a reference made to a test for nitrites in water.

In the description given naphthylamine hydrochloride is mentioned, but there has accidentally been omitted the sulphanilic acid, which is also necessary.

This has probably arisen from its having been mistaken for sulphuric acid, which is also required.

The test is usually performed by adding to the water a solution of sulphanilic acid, then pure sulphuric acid, then a solution of naphthylamine hydrochloride.

Since without the first-mentioned body the

red color of the nitrites does not appear, a serious error might be occasioned.

It would be well, therefore, in the next number of the journal to call attention to this omission.

Yours,

HENRY LEFFMANN, M.D.

PHILADELPHIA, PA., August 6, 1886.

## Notes and Queries.

### WAS IT LEAD PARALYSIS?

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—July 15, C., aged 60, good family history, never sick, addicted to the use of alcoholic stimulants, came to me with wrist-drop paralysis of the extensors of carpus and phalanges of the right hand. The night previous he had gone to bed feeling well, but on arising in the morning he found his hand in the above-described condition.

I questioned him closely, but could find no symptoms of lead colic. Bowels were regular; no pain; appetite good; no metallic taste in mouth; the gums showed no appearance of a blue line.

The only thing that I had on which to base my diagnosis was that he was in the habit of carrying lead seals for freight-cars in his mouth from one car to the other. He had been doing this a number of years. I did not begin treatment for a week, at his request, he thinking it was only a sprain.

I then began the use of the interrupted galvanic current daily, giving strychnine and iodide of potassium internally. In four weeks he was completely cured, and now he says his hand is as good as ever.

The question is, If this was not lead paralysis, as I diagnosed it, what was it?

I would be pleased to hear from some of the many readers of the GAZETTE about this.

J. S. APPLEMAN, M.D.

STRYKER, OHIO.

### HOPEINE.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—You seem to be in considerable doubt about the composition and properties of "hopeine." A judicial decision from this State will settle the matter for you, for, as far as my recollection serves me, about the time of the Centennial the Eastern article was identical, only a little inferior, to the Western.

Under the new prohibition law of Iowa no alcoholic drinks are vended. Hopeine is extensively sold. HOPEINE is on many a sign where saloons were wont to be kept. One of these places was arraigned for illegal selling. Several witnesses were called who affirmed, under oath, that they had partaken of hopeine and nothing else. The case rested. "Do you know," said the judge, to one of the witnesses, "the difference between beer and whiskey when you taste it?" The witness said he did. "Now," said the judge, "you will tell the jury whether hopeine that you drank was beer or whiskey, and you will be committed to jail for contempt until you answer the question." "It was beer," said the witness. F.

\* CLINTON, IOWA, July 24, 1886.

[At last we know what hopeine is. It is not the alkaloid of American hops; it is not morphine, cocaine, or atropine. It is beer.—Eds.]

### PRECAUTIONS AGAINST CHOLERA.

In view of the terrible ravages of Asiatic or epidemic cholera in Europe during the past eighteen months, in which time it has numbered its victims by tens of thousands, and of the fact that it is constantly invading new regions on that continent, showing an especial preference for the shores of the Mediterranean, with which our country has extensive and intimate commercial relations, the State Board of Health of Pennsylvania has deemed it wise to issue a few concise rules, the observance of which will tend to check its spread should it reach our shores. That it has not done so already is not due to any change in the epidemic character of the disease, but simply to the fact that the United States Government has at length awakened to a sense of its responsibilities as the guardian of the health of its citizens, and adopted wiser and more stringent measures than ever before to prevent the scourge from starting on its voyage of destruction. It is too much to hope, however, that it can be entirely shut out, with the limited appliances at present at the command of our authorities. Let not the fact that the warm season is over engender a false sense of security. In one of our recent epidemics the first cases appeared in the month of December, and, with the favoring conditions of the following summer, the pestilence burst forth. It is the part of wise generalship "in time of peace" to "prepare for war," and not wait until the foe is upon us, and mad panic sunders all

ties and paralyzes all resistance. The Board, therefore, suggests as of the utmost importance the following

#### PREVENTIVE PRECAUTIONS.

Filth is the home, nest, and breeding-place of cholera. The removal of filth beforehand is of infinitely more use than its attempted disinfection after the epidemic has begun. To this end it is essential :

1. To examine the condition of all public water-supplies, and, if pollution is discovered, to cut off its source.
2. To examine the surroundings of all private wells with reference to the existence of causes of pollution.
3. To remove all house refuse, offal, and garbage from the neighborhood of habitations, and either bury or burn it.
4. To use copperas, dry or in solution (a pound to the gallon of water), in all places which are in the least offensive.
5. To examine thoroughly all house-plumbing and drainage, and remedy defects.
6. To thoroughly and frequently cleanse all cellars, out-houses, stables, and hog-styes, using whitewash freely.
7. To drain all wet places in the immediate neighborhood of dwellings; and to drain, ventilate, and, if necessary, cement damp cellars.

The organization of local boards of health in every city, borough, and township in the Commonwealth during the coming winter is of the utmost importance to aid in carrying out these suggestions, and local boards already in existence should act with energy and despatch. Should our quarantine authorities, national and municipal, who are, hourly, on the alert to prevent the introduction of this particular disease, be successful in their benevolent, devoted, and patriotic efforts, it will be a satisfaction to know that no pains taken, no labor expended, no expense incurred in improving the sanitary condition of our towns and our homes, will have been wasted. These measures must inevitably result in diminishing the prevalence of other diseases which we have always with us, and which, in the long run, therefore, carry off more victims than cholera in its comparatively short, though terrible, stay. Should it make its appearance, after we have thus put our habitations and surroundings into the complete state of preparation above recommended, we may view it with comparative indifference. It will not be wise, however, in its presence to neglect certain

#### PROTECTIVE PRECAUTIONS.

The cholera poison, whatever it be, is taken into the system through the mouth,—that is, IN FOOD OR DRINK. Simply being near a cholera patient cannot give you the disease. Therefore, have no fear of visiting a cholera-infected house on an errand of necessity or of mercy, or even of nursing a cholera-stricken relative or friend. Still further, there is strong ground for believing that the natural juices of a healthy stomach will destroy the vitality of this poison. In Europe last year the greatest number of new cases were usually reported on Monday mornings, Sunday being the day for dissipation among the working classes, and thus leaving them with disordered stomachs, incapable of destroying the activity of the virus before it reached the bowels, where alone it has the power of doing injury. It is, therefore, of the utmost importance to preserve a vigorous digestion by observing a few simple PERSONAL PRECAUTIONS: (1) Avoid all excesses in food or drink, and especially in alcoholic drinks. (2) Take your meals at regular intervals, and do not go into an infected house on an empty stomach. (3) Avoid all intense excitement, violent exercise, colds from undue exposure, and the immoderate use of ice-water. (4) Do not restrict the range of your diet suddenly or exceedingly. (5) Keep the skin in active condition by frequent bathing of the whole body with tepid water, and never eat without first washing the hands carefully. Cholera rarely attacks those who lead healthy, cleanly lives. Its victims are usually found among the dissipated, the careless, and the dirty.

While thus placing your body in a thoroughly defensive condition, do not overlook the importance of PRECAUTIONS IN REGARD TO FOOD: (1) Look upon unripe or over-ripe fruit or vegetables as so much poison, and do not allow your children to have pennies to buy the half-decayed fruit offered for sale on the street-stands. (2) It has been abundantly proved that heat destroys the potency of the cholera poison. Therefore, use no water for drinking, or for washing cooking and table utensils, which has not been thoroughly boiled. You will also err on the side of safety if you eat no uncooked fruit or vegetables. (3) Milk is especially liable to convey infection, and should, therefore, always be boiled. (4) If you use a filter, see that your water-cooler is rinsed carefully every day, and that the filtering material is frequently washed or changed.

(5) As sulphuric acid has been proven to possess the power of destroying the infectious material of cholera, if there is the slightest reason to suppose that the water is polluted, use the additional precaution of adding a tablespoonful of dilute sulphuric acid to every gallon of drinking water. This quantity will not render the water unpalatable. A little sugar may be added, however, if the acid is distasteful. In case of diarrhoea coming on, this acid mixture may be taken of six times the above strength, and frequently repeated in small doses until a physician can be summoned, which should always be done immediately, if the epidemic is a virulent one, the patient meanwhile remaining on his back. (6) As the infection may be carried in clothing, do not send your own to public laundries. That of cholera patients may be washed in the same water, and the disease may thus be brought back to your own house.

Should a member of your family be attacked with the disease, keep the patient in the house, as removal might be fatal, and send away the well members as far as practicable. Use the following

#### PRECAUTIONS IN THE SICK-ROOM.

(1) All carpets, curtains, and clothing not in use, contents of bureau-drawers and wardrobes, books, etc., should be removed from the sick-room at the earliest possible moment. The infection resides in the discharges of the patient, whether from the stomach or the bowels, but especially from the latter; therefore (2) All such discharges should be received in a vessel containing about a pint of disinfecting solution, thoroughly mixed, and allowed to stand fifteen minutes, if possible, before emptying. If in the country, they should then be buried at least eight inches under ground, and remote from any well or running stream. (3) Any clothing, bedding, towels, napkins, or handkerchiefs, soiled by a patient, should at once be immersed in a strong disinfecting solution, allowed to remain four hours, and then boiled or exposed to dry heat for four hours (230° Fahr.). (4) After the recovery or death of the patient, as much of such clothing as can be dispensed with should be burned. All utensils used by the patient should be placed at once in a disinfecting solution before being washed. (5) During convalescence all the discharges of the patient must be treated as if they were fresh cholera discharges. (6) The dead should be enveloped in a sheet saturated with a disinfecting solution without previous

washing of the body, and at once placed in a coffin. Burial should be immediate and private. The Board recommends the following

#### DISINFECTING SOLUTIONS,

principally suggested by the Committee on Disinfectants of the American Public Health Association:

#### *For the Disinfection of the Discharges from the Patient.*

1. *Standard Solution, No. 1.*—Dissolve chloride of lime or bleaching powder of the best quality (containing at least twenty-five per cent. of available chlorine) in soft water in the proportion of four ounces to the gallon.

2. *Standard Solution, No. 2.*—Dissolve corrosive sublimate and permanganate of potassium in soft water in the proportion of two drachms of each salt to the gallon.

(NOTE.—1. This solution is highly poisonous. 2. It requires a contact of one hour to be efficient. 3. It destroys lead pipes. 4. It is without odor.)

3. *Standard Solution, No. 3.*—To one part of Labarraque's Solution (*liquor sodæ chlorinatae*—U. S. P.) of hypochlorite of sodium add five parts of soft water.

(NOTE.—Competent authority has pronounced this superior to all other disinfectants.)

#### *For the Disinfection of Clothing, Towels, Bedding, and other Textile Fabrics.*

*Standard Solution, No. 4.*—Dissolve corrosive sublimate in water in the proportion of four ounces to the gallon, and add one drachm of permanganate of potassium to give color to the solution as a precaution against poisoning. One fluidounce of this solution to the gallon of water is sufficiently strong. Articles should be left in it for two hours. One gallon of standard solution, No. 1, may also be mixed with nine gallons of water, and used in the same way. No article should be allowed to leave the infected room until it has been either disinfected or boiled.

(NOTE.—Corrosive sublimate solutions should be kept in wooden or crockery vessels.)

#### *For the Disinfection of Water-Closets, Urinals, Sinks, and Cesspools.*

4. *Carbolic Acid Solution.*—Mix one pint of carbolic acid with two and a half gallons of water.

Standard solution, No. 4, diluted with three parts of water, may also be used in the proportion of one gallon (of the solution) to every four (estimated) of the contents of the vault. Standard solution, No. 1, would require to be used gallon for gallon of the

material to be disinfected. Dry chloride of lime may be sprinkled over the contents of a privy, or standard solution, No. 2, may be made up by the barrel, and four or five gallons be applied daily during an epidemic.

*For Disinfection of the Sick-Room after it is Vacated.*

Thorough ventilation for several days, and thorough washing of all surfaces with one of the disinfecting solutions, say, one pint of standard solution, No. 4, to four gallons of water, or a quarter of a pint of solution of hypochlorite of sodium to a gallon of water. The walls and ceiling, if plastered, may be washed with this, and then whitewashed. All dust must be carefully washed (not brushed or swept) away from ledges, cracks, corners, and crevices.

5. *Sulphuric Acid Solution.*—Sulphuric acid or oil of vitriol is often accessible when other disinfectants are not, and is very effective, in the proportion of one ounce to the gallon of water, for disinfecting cholera stuff (discharges); of the same strength for soiled clothing; and of half this strength for bathing the body of the sick or the hands of the attendants, or sponging the clothing of attendants and the floor and carpets, if they become soiled.

*A CASE OF CYSTIC GOITRE TREATED BY "SHELLING OUT."*

MR. WILLIAM DUFF reports the following case in the *Lancet* for July 3, 1886:

Annie Z., aged 23, married, was admitted on July 23, 1885, suffering from a tumor on the right side of the neck. She had enjoyed good health until five years ago, shortly after marriage, when a swelling commenced to form over the right side of the thyroid gland, and continued slowly and persistently to enlarge. She had one child a year and a half ago, but neither pregnancy nor lactation seemed to influence the growth. On admission a tumor about the size of a cocoanut occupied the position of the right lobe of the thyroid gland, and passed somewhat over to the left of the middle line of the neck. The skin, with a few enlarged, subcutaneous veins, was freely movable over the swelling, which moved with the trachea in the act of swallowing. Fluctuation could be felt all over it, more distinct in some parts than others. Neither breathing nor swallowing was seriously interfered with. About three weeks before admission a teacupful of

bloody serous fluid was withdrawn by a trocar and canula, and the tumor was considerably reduced in size, but reaccumulation took place in a day or two. By August 11 the tumor had attained a larger size than ever, the circumference of the neck being seventeen and three-quarter inches. The patient was informed that if the tumor remained serious results might ensue, and she consented to an operation.

Ether having been administered, Dr. Vachell proceeded, on August 12, to remove the tumor under the carbolic spray. A vertical incision, measuring about two and one-half inches long, was made through the skin over the most prominent part, and at once the surface of the tumor came into view, the capsule of the gland, if present, having been so thinned by pressure as to present no difficulty. Up to this point very little hemorrhage had occurred. Without much difficulty the tumor was now shelled out, but the hemorrhage, which commenced with this process and continued throughout, was very profuse. Firm pressure was maintained by an assistant, the surface was mopped with very hot water mixed with tincture of iodine (1 in 20), and as bit by bit the surface was exposed all the bleeding points were ligatured. The edges were then brought together and a drainage-tube inserted.

After the operation the progress was satisfactory. Some sickness in the afternoon and a troublesome cough led to considerable oozing, necessitating the dressing of the wound in the evening. The dressing was repeated the next day. On the 14th the tube was shortened, and on the 16th the stitches were removed. On the 19th boric dressing was substituted, and on the 24th the patient left the infirmary.

The temperature rose on the evening of the day of the operation to 103.8°, and remained more or less febrile till the 19th. Probably this was due to an attack of bronchitis, from which she then suffered.

The tumor, which was irregularly ovoid in shape, measured thirteen inches by nine inches, and weighed twenty ounces. On being cut into, nine ounces of dark sanguineous fluid escaped, similar to what had been removed by tapping, but darker. The walls varied from one-sixth of an inch to rather over half an inch in thickness, and consisted of material resembling heart muscular fibre in naked-eye appearance. The internal surface was much and deeply corrugated.

## ATROPINE-POISONING.

JULIUS KRATTER records in *Schmidt's Jahrbücher* of June 1, 1886, his observations made in eight cases of poisoning by atropine or belladonna treated in the hospital at Graz. The first case was a slight poisoning provoked by seven powders of 0.01 grm. ( $\frac{1}{10}$  grain) of the extract of belladonna; the second, a grave intoxication caused by seven suppositories of 0.05 grm. (1 grain) of the same extract; the third, fourth, and fifth cases, all of which were likewise serious, were the result of eating the berries of belladonna by mistake. In the sixth case, an auto-intoxication by the berries of belladonna, maniacal phenomena presented themselves, followed by a profound coma, and death on the third day.

The clinical appearances deviated but little from the well-known group of symptoms of atropine-poisoning. In several cases the dilatation of the pupil was the first symptom observed. Kratter emphasizes the fact that in all these cases the temperature was distinctly elevated, though all text-books speak of a reduction of the temperature in atropine-poisoning. In a case observed by Fritz Strassmann, of Berlin, the temperature was likewise found to be raised. *Vide Schmidt's Jahrbücher, loco citato.*

## ADMINISTRATION OF TEREbene.

The following formulæ for preparations of terebene are taken from the *Colonial Druggist* (reprinted in *Nat. Drugg.*), and will be found convenient to druggists, for they are usually applied to by the physicians for the proper combinations to administer new remedies (*American Druggist*, July, 1886):

Terebene is employed as a remedial agent not only in cases of "winter cough," phthisis, dyspepsia, etc., as related by Dr. Murrell, but also in various affections of the alimentary canal, in certain skin-diseases, and as a disinfectant; this has naturally created a considerable demand for this preparation.

The ordinary mode of taking terebene—"10 drops upon a lump of sugar"—has several disadvantages, not the least of which is that the sugar, if thoroughly impregnated with the hydrocarbon, is rendered—for some time at least—practically insoluble in water or saliva; it has, therefore, either to be crushed by the teeth and well masticated, or else retained in the mouth for an inconveniently long period. The linctus given below will be found far more convenient, as well as more palatable:

**R** Terebene, f3v;  
Powdered gum-arabic, f3iv;  
Syrup of tolu, f3i;  
Strained honey, f3ii;  
Tincture of saffron, q.s.;  
Water, q.s.

Mix intimately in a small mortar the terebene and the powdered gum; emulsify carefully with  $1\frac{1}{2}$  ounces of the water, adding the syrup of tolu gradually towards the last. Stir in the honey until the whole has become smooth; make up to the measure of 6 fluid-ounces, and color with a few drops of the tincture of saffron. The dose is one teaspoonful. This linctus keeps well, and is generally appreciated, even by young children, while in a variety of throat affections it gives speedy relief, although free from narcotics; observations which also apply to

## TEREBENE COUGH MIXTURE.

**R** Terebene, f3i;  
Powdered gum-arabic, 3iv;  
Powdered sugar, 3iii (troy);  
Yolk of eggs, 2;  
Anise water, f3ii;  
Camphor water, f3iv;  
Distilled water, q.s.

Mix the two powders in a mortar, and stir in the terebene. Emulsify with the yolk of eggs, and the aniseed and camphor waters previously well beat up together. When perfectly smooth, make up with water to the measure of 8 fluidounces. Dose: One teaspoonful as often as may be necessary. An acidulous modification is as follows:

**R** Terebene, f3i;  
Powdered gum-arabic, grs. xxx;  
Powdered sugar, 3i (troy);  
Yolk of eggs, 2;  
Syrup of lemon, f3iii;  
Water, q.s.

Proceed as previously directed, only emulsify with a very little plain water before adding successively the yolk of eggs and acid lemon syrup. If the eggs be not "new laid," it may be as well to beat up the yolks with about 20 or 30 minims of diluted phosphoric acid before stirring the same into the other ingredients, as before. Make up to 8 ounces. Both this and the preceding mixture may be tinted, if desired, with a little saffron or caramel.

This mixture should contain about 16 grains of citric acid to the fluidounce; therefore, if the lemon syrup used is not strong enough in this respect, a little powdered citric acid must be added to make up the deficiency.

## PASTILLES OF TEREbene.

- R Terebene, 80 to 100 grms. (1 gr.= 15 grs.);  
 Gum-arabic, 400 grms.;  
 Powdered tragacanth, 200 grms.;  
 Powdered loaf-sugar, 500 grms.;  
 Glycerin, 30 grms.;  
 Oil of lemon, 12 grms.;  
 Egg (white of), 5 or 6.

Dissolve the oil of lemon in the terebene, and add the mixture to all the powdered gums and 100 grammes of the sugar. When thoroughly incorporated, emulsify with the smallest convenient quantity of water, and add the glycerin and the egg albumen, the latter having been well whisked. Transfer to porcelain or enamelled iron vessel heated by a water-bath, and, when warm, slowly sift in the fine sugar as it dissolves in the viscous fluid. Stir constantly, and evaporate until a little dropped upon a cold plate becomes, after ten minutes, of a sufficiently firm consistence. Pour out to the depth of about half an inch upon cold tin or porcelain plates, which have first been dusted over with finely-sifted dry starch. When cool, divide the stiff, dough-like mass into squares or diamonds of suitable dimensions, using a mixture of one part white sugar and three parts starch, perfectly dry and in fine powder, to prevent sticking. A small sugar-sifter, or "dredger," will be needed during this operation. These pastilles may be safely given to the youngest children, and for persons of old age are very efficacious in dislodging both phlegm and flatus.

## AROMATIC TEREbene FOR DISINFECTION.

- R Terebene,  $\text{Zii}$ ;  
 Eucalyptol,  $\text{Ziii}$ ;  
 Thymol,  $\text{Mxx}$ . M.

Put up in "sprinkler" bottle, and impregnate small pads of cotton, wool, bran, "wads" of lint, blotting-paper, etc., and hang them about the apartment some two and a half to three feet from the ground, especially in such situations where a draught from door or window is likely to cause currents of air to pass over them occasionally.

## AROMATIC TEREbene SPRAY.

The disinfecting mixture just mentioned, either by itself, or, preferably, dissolved in an equal bulk of strong alcohol, or Larbalestier's eau de cologne, is shaken up in an atomizer with ten parts of plain water. When "sprayed," a refreshing fragrance is imparted to the air, and septic fermentation cannot take place therein.

## THE INFLUENCE OF GASTRO-INTESTINAL AFFECTIONS OF CHILDREN ON THEIR BODILY WEIGHT.

DR. NAKATSU MIYAMOTO (of Japan) communicates to the *Arch. f. Kinderheilkunde*, 1886, vol. vii., Nos. 3, 4, the results of his observations on the influence of gastro-intestinal troubles of children on their bodily weight. He examined for the purposes stated, dyspepsia, ten cases; intestinal catarrh, fifteen cases; enteritis follicularis, eight cases; cholera infantum, six cases. His conclusions are thus formulated: (1) dyspepsia invariably and manifestly decreases the weight, often causing a daily loss of thirty-three grammes (one ounce). (2) Intestinal catarrh has very similar consequences. (3) In enteritis the loss is far heavier, at times amounting to twenty ounces *pro die*. (4) Cholera infantum causes, of all stated affections, the greatest reduction in weight in the shortest time, amounting occasionally to a loss of one-tenth of the entire weight within twenty-four hours. These cases, of course, are all fatal.

## REMARKABLE ACCIDENT WHILE TAPPING A HYDROCELE.

A rare and remarkable accident during the ordinary operation of tapping a hydrocele is reported from Bordeaux. The patient was a healthy peasant of 44 years of age, who had never suffered from any venereal affection. The hydrocele, which was on the right side, had been in existence some two years, and had followed an accidental blow. As it continued to increase in size, he sought advice, and was admitted into M. André Boursier's clinic. When the trocar was introduced, about one hundred and twenty-five grammes of straw-colored fluid came away. M. Loumeau, who performed the operation in M. Boursier's presence, then, having satisfied himself that the extremity of the canula was free in the cavity of the tunica vaginalis, proceeded to inject gently 60 grammes of a mixture of tincture of iodine with twice its volume of water. All at once the patient complained of severe pain in the cord and the loins, with cramp in the right forearm. The ulnar border of the right hand then became flexed, the ring and small fingers being completely flexed, while the index and middle fingers, though extended as far as the second and third phalanges were concerned, were flexed at their metacarpo-phalangeal articulations. The thumb also was flexed and brought near the fingers. Exactly the same position was shortly

afterwards assumed by the left hand. There were no convulsions or syncope. After a few minutes the "ulnar *griffe*" began to relax, and the index and middle fingers became flexed completely on the hand, which itself became strongly flexed on the forearm. All the muscles on the front of the forearm became hard and contracted. The palmar fascia was strongly retracted, and the palmaris brevis quite tense. On both sides the ulnar affection had given place to contraction of the muscles supplied by the median nerve. The patient was unable to articulate a sound, his tongue hanging loosely in the buccal cavity. The muscles supplied by the hypoglossal nerve were also contracted, but for a short time only. The forearms were shampooed, and after nearly an hour the muscles relaxed. The patient recovered completely, and left the hospital after a few days. M. Loumeau has been unable to find an example of this kind in medical literature; but M. Desplats, of Lille, published a paper on pleural eclampsia last year in the *Semaine Médicale*, in which he refers accidents connected with pleural operations to four categories: (1) toxic action of the liquid injected, (2) true epilepsy, (3) uræmia, (4) reflex action. The author surmises that the accident was due to reflex irritation of the nerves of the serous membrane by the liquid injected. The testicle, it may be remarked, was in no way injured. Whatever explanation may be offered, the fact remains, which is itself sufficiently extraordinary, of a healthy peasant man of middle age being thrown into a state of severe nervous spasm by the performance of a very simple and very common surgical proceeding.—*Lancet*, July 3, 1886.

#### TUBERCLE-BACILLI IN THE URINE.

DR. KIRSTEIN reports in the *Deutsche Med. Wochenschrift* (1886, vol. xii., No. 15, p. 249) the clinical history of a case of grave septic cystitis in which, by the discovery of tubercle-bacilli in the urine, he could diagnose the simultaneous existence of tuberculosis of the bladder. The copious sediment, consisting chiefly of septic and purulent matter, rendered the recognition of the bacilli of course extremely difficult. They could only be found in one out of forty sections. To facilitate the finding of the microbes, Kirstein proposes the following procedure: The sediment is transferred to a cup-shaped glass, well stirred with a glass rod and filtered; then the residue is

poured on a watch-glass, some of the matter crushed between two slides, and treated in accordance with Ehrlich's method. The result of this procedure was the finding of bacilli in each of the preparations thus obtained.

#### POISONED BY WILD FLOWERS.

About a fortnight since, a little girl, aged 7 years, died at Glasgow, as alleged, from having sucked the bloom of some poisonous wild flower. The child had been taken on a Sunday-school excursion into the country. During their ramblings wild flowers were gathered, and posies were arranged and garlands woven, as is the wont with children set free from the care and discipline of schools and allowed to roam fancy free in meadows and by hedge-rows. In their delight at nature's fairest gifts, little did the denizens of the big Scotch town dream of the poison that lurks within the spathe of the cuckoo-pint (*Arum maculatum*), or in the clusters of purple blossoms of the woody nightshade (*Solanum dulcamara*). In fact, the flower of this plant is so like in form and arrangement to that of its innocent first cousin, the esculent potato, that we can understand how a knowledge of the harmlessness of the culinary tuber may have suggested a riskless indulgence in the flowerets of the former. In these days of school-board exaction, is it too much to ask that our children should be instructed, if only in simple fashion, in the broad principles of botany and zoology, and taught how to recognize the plant that nourishes and the one that kills,—the harmless snake and the poisonous adder? It is not necessary to go into technical details and to use harsh scientific words to instil into a child's mind that which may be of good service to it when brought in contact with the floral beauties of spring and early summer, or with the berry clusters of a later season. What could be more interesting to a hard-worked, brain-wearied little wanderer in God's garden than to learn the way to recognize the difference between the garnishing parsley and its deadly relative whose name is the antithesis of him that is wise, or its still more poisonous effigy, the classic hemlock, growing in shady nooks? We might mention a hundred other instances,—e.g., the creeping hairy bryony, with its festooned wreaths of scarlet berries, hard by its rival, the common tamus, with leaves of shining green, growing bronzed and sombre as the autumn of its vegetative life approaches. We could tell that the simple

dropwort, or spiræa, has no right to have its title disputed by the water dropwort or the hemlock water dropwort, with which it holds no natural affinity. We could warn against the perfidy of the gaudy foxglove and the sedate but deadly nightshade, and so on; but enough has been written to merit the sympathy of our Board of National Education, and to make them consider that the fields around us are the true fields of learning.—*Lancet*, June 26, 1886.

*ON LESIONS OF THE CORNEA FOLLOWING THE INSTILLATION OF COCAINE.*

Numerous instances have now been recorded in which the use of cocaine has been followed by local ill effects: these may be divided into two classes, namely, suppurative panophthalmitis and lesions of the cornea. The former being, in all probability, due to septic infection, cannot be said to depend directly upon the use of cocaine, except in so far as cocaine increases the absorbent properties of the cornea (a subject that will be considered presently), and direct inoculation occurs from impurities in the solution used.

The corneal lesions which have been observed are of two kinds: (1) an affection of the epithelial layer only, consisting of vesication or desquamation, and (2) interstitial opacities, often taking the form of a kind of striated keratitis extending from the wound.

One of the first to observe the superficial changes was Paul Bunge (*Klin. Monatsbl. für Augenheilk.*, 1885, p. 402), and very many instances have been recorded since. In some of these, the case has not been complicated by the employment of any antiseptic solution, a point which, as will presently be seen, is of considerable importance. There can, therefore, be no question that the vesication and desquamation which occasionally follow the use of cocaine are really due to the action of the drug.

With the view of ascertaining how cocaine produces this effect, Würdinger has recently conducted some experiments upon animals (chiefly rabbits, but also upon dogs and guinea-pigs) (*Klin. Monatsbl. für Augenheilk.*, April, 1886). In addition to the anæsthetic action of cocaine, one of its most marked effects is the dryness of the surface of the eye which it causes; this is probably due chiefly to the anæmia of the conjunctiva and the diminution in the lachrymal secretion from constriction of the blood-vessels; but it is probably increased by the wide opening of

the palpebral fissure that usually occurs, and the absence of the natural and involuntary blinking movements.

In order to ascertain how far the changes in the corneal epithelium were due to these causes, Würdinger instilled a drop of a five per cent. solution into both eyes of a rabbit, at intervals of four minutes. The one eye was kept closed between the instillation, but the other remained open.

In the closed eye, no changes whatever took place in the appearance of the cornea. In the other eye, after three or four minutes, slight changes were noticed; these increased, and, in twenty to twenty-five minutes after the cocaine had been commenced, the cornea presented a superficial and fine roughness, as well as depressed areas, which looked as if they were caused by the shedding of the epithelium. After an hour, the turbidity of the cornea had increased so much that the condition of the iris could no longer be made out.

Further experiments showed that the intensity of the changes depended more upon the duration of the experiment than upon the concentration of the solution, or the frequency with which it was applied. By dropping distilled water upon the cornea, between the applications of the cocaine, changes which had already occurred were not removed, but their increase was prevented. Microscopic examination of the altered areas showed that the epithelium, where not removed, was thinned out, and that there was also considerable thinning of the anterior layers of the true corneal tissue.

As regards the interstitial opacities of the cornea, Dr. Wood-White (*Ophthalmic Rev.*, January, 1886, p. 6) appears to have been the first to suggest that they were due, not to the cocaine itself, but to the simultaneous employment of a solution of corrosive sublimate. He states that he has frequently used cocaine alone, and in conjunction with boracic acid, and has never seen any ill effects arising from it, but that in the only cases in which he at the same time used a solution of corrosive sublimate (five cases of cataract extraction), a pearly-white opacity, extending from the wound, was visible on the second day; this cleared up completely in all the cases in a few days.

Dr. Wood-White has omitted to state the strength of the solution of corrosive sublimate used by him, and also whether he has used the same solution alone in other cases; but, assuming that the solution was of the strength ordinarily employed, the conclusion seems a reasonable one that the effect produced was

in some way dependent upon the combined action of the cocaine and corrosive sublimate; and some of Würdinger's experiments appear to support this.

Dropping fluorescein into a cocainized and into a non-cocainized eye at the same time, Würdinger found that in the non-cocainized eye only the superficial layers became fluorescent, but that in the cocainized eye the deeper layers also became affected. When the epithelium was removed from a limited area, and "methyl-blau" was dropped upon the abraded surface, it alone became colored in the non-cocainized eye, while in the cocainized eye the coloring matter extended through the whole cornea. It seemed clear, therefore, that the effect of the cocaine was to increase the absorbent power of the cornea. Finally, Würdinger found that weak solutions of boracic acid, corrosive sublimate, and even of common salt, which in the normal eye were perfectly innocuous, in the fully-cocainized eye produced a turbidity of the cornea, identical with the early stage of the striated keratitis which sometimes follows cataract extraction.

If subsequent experiments should verify these conclusions, it is evident that the views at present held as to the advisability of employing corrosive sublimate as an antiseptic will have to be considerably modified. It is of the utmost importance that these investigations should be carried further, in order to ascertain what is the weakest solution of corrosive sublimate capable of producing the lesions described, and the weakest that is efficient as an antiseptic. In the mean time steps should be at once taken to ascertain whether any interstitial lesions of the cornea have ensued when cocaine has been used alone. It is significant that most of the reported cases have been furnished by institutions in which corrosive sublimate is used as a matter of routine; but in many instances it is not stated whether it was actually used or not, the point not being considered of any importance at the time of publication.—*British Medical Journal*, August 7, 1886.

#### THE INCOMPATIBILITY OF CHLORAL WITH POTASSIUM BROMIDE AND ALCOHOL.

We have in previous issues referred to the peculiar incompatibility exhibited by chloral in the presence of potassium bromide and alcohol, and have given the experiments of PROF. MARKOE in explaining this, together

with the various criticisms which his statements called forth. Prof. Markoe again replies to his critics in the *Pharmaceutical Record* for June 15, 1886. The original prescription in which the incompatibility was first noted was composed of the ingredients shown by the following copy:

R Potass. bromid.,  
Chloral hydrat., āā ʒiii;  
Tr. opii et camph.,  
Syr. zingiber., āā ʒiss. M.

S.—One or two teaspoonfuls in half a wineglass of water every two to six hours. For sleep.

When this mixture is made up, it always results in the formation of two layers,—a dark-colored liquid floating upon a light-colored denser liquid.

The writer explained this decomposition as due to the change of the chloral hydrate into the less soluble chloral alcoholate, the alcohol being furnished by the paregoric elixir called for in the prescription.

Three experiments were then detailed, in which the endeavor was made to prove that the alcohol was the sole cause of the trouble.

These experiments were printed in the following form in the volume of the Proceedings, as well as in all the reprints of the paper:

1. Potass. bromid., grs. lx;  
Chloral hydrate, grs. lx;  
Water, ʒvi;  
Syrup of ginger, ʒvi.

These articles formed a perfect solution, which did not separate on standing.

2. Potass. bromid., grs. lx;  
Chloral hydrate, grs. lx;  
Water, ʒiii;  
Alcohol, ʒiii;  
Syrup of ginger, ʒvi.

In this experiment it will be noted that the ingredients differ from the original only in the substitution of diluted alcohol for the paregoric. After standing a short time this mixture separated into two layers, the upper being of a light straw color.

3. This experiment was with the same ingredients as in No. 2, except that the alcohol was not added until after the mixture had been standing an hour. No separation took place before the addition of the three fluidrachms of alcohol, but the separation occurred promptly after the addition of the alcohol. These experiments prove that the alcohol is the cause of the trouble, and the writer thinks that the chloral hydrate is

changed into the less soluble chloral alcoholate.

A careful reader would have readily seen that the writer's intention was to take just one-half the quantity of the original prescription for the experiments 1, 2, 3, which would require 90 grains of each of the salts ordered in place of the 60 grains as printed. Most of the critics did not take the trouble to try the experiment with the original prescription, but repeated experiments 2 and 3, using only 60 grains of each of the salts, and, finding no separation, at once jumped to the conclusion that the thing was all wrong. The misprint, due to a blunder in making hectograph copies of the original paper, was corrected in some of the pharmaceutical journals.

An English critic, in a very courteous note to the *Pharmaceutical Journal*, took exceptions to the statement that alcohol was the sole cause of the decomposition, and claimed that the presence of sugar was necessary for the separation of the chloral compound.

The following experiments will dispose of this criticism :

4. Potassium bromide, grs. xc;  
Chloral hydrate, grs. xc;  
Water, fʒiv;  
Alcohol, fʒii.

The salts were dissolved in the water, forming a clear solution; on the addition of the alcohol and shaking together, the mixture became milky, and on standing separated into two layers, the upper forming somewhat more than a fourth of the whole.

5. Like No. 4, but having three fluidrachms of alcohol; behavior like No. 4.

It will be seen, therefore, that the presence of sugar is not needed to produce the separation of the chloral; it is only necessary that we have very strong solutions of chloral and bromide. The addition of more alcohol, or dilution with water, will restore a perfect solution of the separated chloral compound.

The presence of sugar will greatly facilitate the decomposition, by allowing it to take place in weaker solutions.

#### TREATMENT OF ANGIOMA.

DR. BÖING has treated five cases of angioma in children of 2 to 9 months old by daily brushing the tumor with a four per cent. solution of sublimate collodium for four consecutive days. The result was in each case very successful.

#### POISONING BY SAUSAGES.

Familiar as is poisoning by sausages, there yet remains much to be learnt of the manner in which the poison or poisons act. Sometimes an inorganic poison has been suspected, but generally it is supposed that the deleterious agents are in some way related to the occurrence of decomposition in the organic contents of sausages. NAUWERCK, of Tübingen, has investigated a series of cases of poisoning by sausages, and has come to the conclusion that the symptoms were to be largely attributed to the agency of certain complex bodies that are known to be derived from the decomposition of albumen. Some of the symptoms of sausage-poisoning are of considerable interest, such as the paralysis of accommodation for near objects of vision, also the dilatation of the pupil and drooping of the upper eyelid. It does not follow that sausages are harmless because a chemical examination of them has failed to detect poison in sufficient quantity to prove noxious to the organism. The sausages in these cases may simply contain the germs of decomposition, and not begin to decompose until they have reached a suitable site in the intestinal canal of their host. If all sausages contained poison ready formed at the time of ingestion, it would be difficult to understand how it happens that a considerable period of time occasionally elapses before the symptoms of poisoning commence. A study of the mode of action of the various poisons that are evolved during the process of decomposition of albumens has proved of great service to the science of pharmacological physiology.—*Lancet*, August 7, 1886.

#### LEAD IN TINNED PROVISIONS.

DR. RABCHEVSKI, of St. Petersburg, has published the results of a series of investigations made on various kinds of tinned provisions, with the view of determining the suitability of food preserved in this way for the purposes of the army commissariat, especially when on active service. He first examined the tinned plates in the preserved provision manufactories, and found them in all cases quite free from lead. The case of the solder was of course different, the amount of lead contained in it varying from sixty to seventy per cent. The chemical examination of the contents of the tins was conducted by Pouchet's method, and showed that while some classes of food, such as roast meat, were quite free from lead, others, such as sour cabbage,

which to a Russian is a very important article of diet, contained very appreciable quantities of lead, in one case as much as 0.327 per cent.; so that a man taking 200 grammes, or about a quarter of a pound, of this for his dinner would introduce into his system 0.654 grammes, or about 8 grains, of lead,—a quantity which, especially if taken frequently, can by no means be considered as harmless. The conclusion arrived at by the author is that these tinned provisions should only be used in the army in case of urgent need, and for a very short time. It would appear, too, that a choice might be made; only such classes of preserved food being accepted by the authorities as were shown to be least likely to become contaminated by the injurious substances contained in the solder.

#### GASEOUS MEDICATION PER RECTUM.

The ingestion of gaseous medicines by the lower bowel was the subject of a recent communication by M. L. BERGEON to the Paris Academy of Sciences (*Comptes Rendus*, July 12). His research has extended to a variety of diseases, but for the present he only records his experience in the treatment of pulmonary phthisis. After having tried a variety of balsamic substances of parasiticide or antiseptic repute, M. Bergeon gave the preference to sulphurous mineral waters (Eaux Bonnes, Challes, etc.). A current of from four to five litres of carbonic acid gas traversing from two hundred and fifty to five hundred grammes of the sulphurous mineral water was introduced per rectum twice in the twenty-four hours. After a few days' use, cough was notably diminished and almost suppressed, the expectoration greatly modified in quality and quantity, the sweating stopped, and the general state improved; and that not only in incipient, but also in confirmed phthisis. Daily auscultation established the disappearance of moist râles.—*Lancet*, August 7, 1886.

#### ON HYPNONE.

We learn from the *Munch. Med. Wochenschr.*, vol. xxxiii., No. 14, 1886, that LEUBE has seen good results from hypnone, which he gave to fourteen patients for some time every evening in the dose of 2 to 4 drops in gelatin-capsules. Four, and even 2 drops, sufficed usually to procure a quiet sleep lasting several hours. In phthisical patients the drug seemed to act particularly well. Its action appears one-half to one and a half hours after its in-

gestion. Untoward effects were not observed except in one instance, where 6 drops caused headache and vomiting after a prolonged sleep.

#### BROMINE IN DIPHTHERIA.

SEÑOR LOVAT A. MULCACHY, of Buenos Ayres, finds great advantage in cases of diphtheria in giving a solution of bromine. The bromine is simply dissolved in water in the proportion of 1 to 2500. A teaspoonful of this is given every ten minutes. He says that children will swallow it automatically even when asleep. For infants under three years of age the strength may be diminished to half that mentioned above. He cites several cases showing the successful results obtained by this method, but he points out the importance of the administration being continued for some days, and of the medicine being given exactly every ten minutes. As to local caustic applications, he considers that they serve no purpose whatever, but only irritate and distress the patient.—*Lancet*, August 14, 1886.

#### THE FUNCTION OF THE TONSILS.

DR. R. HINGSTON FOX, in an interesting article on the Functions of the Tonsils, in the twentieth volume of the *Journal of Anatomy and Physiology*, expresses the opinion that these glands belong to the digestive and not the respiratory tract, and that their function is to reabsorb certain constituents of the saliva in the intervals of meals which would otherwise be wasted. He thinks that the view of their having an absorbing function is further supported by the strong evidence of the power of the tonsils to absorb morbid poisons directly from the saliva.—*Lancet*, July 24, 1886.

#### ANTISEPTIC PAPER DRESSING.

DR. DON ANTONIO MORALES PEREZ describes in the *Revista Médica* of Seville a simplified antiseptic or Listerian dressing, consisting of bibulous paper heated to 110° C. and soaked in a solution of carbolic acid, boracic acid, or corrosive sublimate. This is placed over the wound in about eight layers, and covered with sheet gutta-percha or mackintosh, the whole being secured by an india-rubber bandage. The writer claims for this dressing the advantages of cheapness and portability, and thinks it will be found very serviceable in the field and in small hospitals.—*Lancet*, August 21, 1886.

### ON VEGETABLE DIET AND ON FATTY FOODS.\*

BY PROFESSOR DUJARDIN-BEAUMETZ, PARIS, FRANCE.

GENTLEMEN,—If man claims a variety of aliments from the animal kingdom, equally important are those furnished by the vegetable kingdom. Considered as a whole, these vegetal foods contain as elements suitable for nutrition, 1, certain albuminoid substances,—gluten, vegetable albumen, casein,

legumen, and fibrin; 2, starch; 3, dextrine and glucose; 4, fatty matters; 5, salts and water.

Foods thus constituted become complete aliments,—i.e., aliments which contain all the primordial elements necessary for nutrition; only the vegetal proteids, the salts, and the fatty matters are in quantity insufficient to sustain life, at least in man, while, on the other hand, sufficing for the herbivora. The word *insufficient* is not even altogether applicable to man, for there are whole populations that are strictly vegetarian. In order, however, fully to meet the requirements of the economy, a great quantity of vegetable aliments must be ingested to supply the twenty grains of nitrogen which a man loses daily.

\* A lecture on Hygienic Therapeutics, delivered in Cochin Hospital. Printed from advance sheets.

The advantages of an exclusively vegetable diet have been latterly much overrated. We have heard it affirmed that by perseverance in such a diet man might successfully resist most diseases, and attain to a great age ; this is the doctrine of vegetarians. While recognizing the great benefits which may be derived from a purely vegetable diet in certain affections of the stomach, I believe that man, by his anatomical and physiological constitution, is omnivorous, enjoying the fullest possession of his powers on a mixed diet ; on this subject I shall hereafter have more to say.

The albuminoid principles of vegetables have been well studied by Ritthausen. They consist of vegetable albumen, casein, legumen, gelatin, gluten, and congluten. As for gluten, its composition is very complex, and Ritt-hausen affirms that it is made up of at least four albuminoid substances,—gluten-casein, insoluble in alcohol, and three substances soluble in alcohol,—gluten-fibrin, gliadine, and mucedine.

I give you here from Ritthausen the ultimate analysis of these vegetable albuminoid substances, as obtained from various cereals and legumes :

	Wheat.	Barley.	Indian corn.	Lupines.	Peas.	Beans.

Oxygen.....	20.55	22.98	.....	21.91	21.75	21.75

If you glance over the following table, which gives the proximate composition of our principal amylaceous foods, you cannot fail to observe that in general the amount of starch is in inverse proportion to that of the azotized matters :

In the vegetable alimentation starch and the amylaceous principles play an important part. You know that they are absorbed in the state of glucose, and that the transformation of starch into glucose is the result of two ferments,—the one, the product of mixed saliva, is the salivary diastase ; the other, which belongs to pancreatic juice, is amylopsin.

This transformation of starch into sugar is not as simple as one might imagine at first sight. The supposed breaking up of the starch molecule into one molecule of dextrine and one of grape-sugar is not a representation of the reality, if we may trust the experiments of Musculus, of O'Sullivan, of Brown and Heron, and of William Roberts.

According to these experimenters, we must consider this reaction as much more complex, and as terminating by the formation of maltose and achro-dextrine, as the following formula shows :

Ewald, of Berlin, has recently studied the influence which saliva exercises upon the saccharification of amylaceous matters in the stomach. He has shown that the transformation of starch into sugar is effected to a very trifling extent in the stomach, and that after the administration of a concentrated decoction of starch you may note the presence of fermentable dextrine and maltose, but that the metamorphosis of maltose into sugar takes place only in the intestine. If to the facts attested by Ewald we add that the pancreatic juice furnishes a ferment adapted to the digestion of amylaceous matters, we are warranted in the conclusion that starchy sub-

Ritthausen's Table of the Composition of Amylaceous Aliments.

stances are exclusively digested in the intestine.

There is always an interest in knowing (and this especially with reference to the treatment of certain affections, and glycosuria in particular) the quantity of starch contained in cereals as vegetables. The following table from Nedats gives the percentage of starch in wheat, rye, potatoes, etc. :

	Per cent.
Rice.....	74.10
Indian corn.....	65.90
Wheat flour.....	63.00
Whole wheat.....	59.60
Rye flour.....	59.84
Millet.....	59.90
Buckwheat .....	50.00
Wheat bread.....	42.70
Oatmeal .....	39.10
Peas.....	37.00
Rye bread.....	36.25
Beans.....	36.00
Jerusalem artichokes.....	16.60
Potatoes.....	15.50

We will now study successively cereals, legumes, and fruits.

The cereals serve as the basis of the principal food, the universal food, of man,—bread. Without entering here into the details and complex chemical reactions of bread-making, I must call your attention to the nutritive value of bread. In this respect it is important to distinguish the crust from the crumb ; the crust is much the more nutritious, as the following analysis by Barral shows :

Water.	Crust.	Crumb.
Water .....	17.15	44.45
Insoluble azotized matters (gluten, etc.).....	7.30	5.92
Soluble azotized matters (albumen and the like).....	5.70	0.75
Soluble non-azotized matters (dextrine, sugar).....	4.88	3.79
Starch .....	62.58	43.55
Fatty matters.....	1.18	0.70
Mineral matters.....	1.21	0.84
	100.00	100.00

It is generally believed also that bread made from the coarser, inferior flours is more nutritious than bread made from superfine flour. This is a mistake, and Violet has shown us that the finer and whiter the flour the more nitrogen it contains. This is Violet's table :

	Percentage of nitrogen.		
	Second quality.	First quality.	Superfine.
First sample.....	0.92	1.18	1.39
Second sample.....	1.05	1.36	2.06
Third sample.....	0.99	1.02	1.25
Average .....	0.99	1.15	1.57

Nevertheless, in placing ourselves on a somewhat different stand-point, and in judging the nutritive value of bread not by the quantity of nitrogen which it contains, but by that of its saline principles, bread made from flour that is incompletely bolted possesses certain advantages.

You know, in fact, that the husks of grains are especially rich in phosphates ; hence it has been recommended in certain cases, where it is desired to introduce phosphates into the economy, to give bran bread. When I come to speak of the dietetic treatment of diabetes, I shall show you by what artifices ordinary bread has been replaced by bran bread, or, better still, by gluten bread.

Rye, Indian corn, buckwheat, and even oats have been substituted for wheat in the fabrication of bread. Two of these deserve special mention. Corn bread is exceedingly nutritious. Cornmeal contains a larger proportion of fatty matters than the flour of any other cereal ; hence it is that corn bread occupies a large place in the dietary of certain peoples, especially in regions where wheat cannot be raised. It has, however, a peculiar taste, which renders it repugnant to most persons, at least till they become accustomed to it. Oatmeal has been highly vaunted by the Scotch physicians, who claim that the fine physical development of that nation is due to the fact that they are reared on oatmeal. In a work undertaken by me, in conjunction with Ernest Hardy, I have shown the large proportion of nitrogen contained in oatmeal. The following analysis, published by ourselves, will make this plain :

Water.....	8.7
Fatty matters.....	7.5
Starch.....	64.0
Azotized matters, gluten.....	11.7
Mineral matters.....	1.5
Cellulose, and other matters not determined.....	6.6
	100.0

Hence it is that in the feeding of horses, oats, by reason of their richness in nitrogen, have been considered the force-giving aliment *par excellence*. Add to this that oats contain a particular excitant principle, which Sanson has isolated, and the effects of which he has studied. This excitant principle is found especially in black oats, and its effects on the horse last, on an average, for an hour after giving a quart of oats. The large percentage of iron in oats is also worthy of note.

This double quality of being a strengthen-

ing and excitant aliment renders oatmeal suitable for the dietary of children, and you will find in the thesis of my pupil Marie\* interesting facts relative to this subject. I believe even that we might to-day complete our researches by studying on man, as Sanson has done on horses, the effects of the excitant principle, which he has isolated, and seeing if it may be utilized in therapeutics.†

Vegetables are divided into starchy and herbaceous. Starchy vegetables (legumes,—*i.e.*, beans, peas, lentils) contain a great quantity of legumine, and for this reason are very nutritious. Hence it is that beans have been called the *poor man's meat*. The following analysis is from Boussingault :

#### COMPOSITION OF SEEDS OF THE LEGUMINOSÆ.

	White beans.	Peas.	Lentils.	English beans.
Legumine .....	26.9	23.9	25.0	24.4
Starch and dextrine...	48.8	59.6	55.7	51.5
Oily substance.....	3.0	2.0	2.5	1.5
Lignine and cellulose.	2.8	3.6	2.1	3.0
Salts.....	3.5	2.0	2.2	3.6
Water.....	15.0	8.9	12.5	16.0
	100.0	100.0	100.0	100.0

The husk which covers these seeds is composed exclusively of cellulose, which renders them somewhat indigestible. So when you have to do with weak stomachs, or persons who masticate imperfectly, you should direct them to eat their beans or peas hulled, and boiled into a mash or soup.

Among these legumes I must call your attention to lentils, which deserve especial mention from the point of view of their nutritive value, being not only rich in azotized matters but also containing much iron.

Boussingault, who has given us a very instructive analysis of different aliments with respect to the iron which they contain, has assigned the first place to lentils ; in fact, the proportion of this metal in lentils is double that which is found in beef, although surpassed by oats :

	Quantity of iron in 1000 parts.
Beef's blood.....	0.03750
Blood of swine.....	0.06340
Muscle of beef.....	0.00480
Muscle of veal .....	0.00270
Muscle of fish (Merlan).....	0.00150
Fresh codfish.....	0.00420

\* Marie, "A Study on the Employment of Oatmeal" (*Thèse de Paris*, 1873).

† Sanson, "Experimental Researches on the Excitant Action of Oats" (*Four. d. Anat. et de Phys. de Ch.* Robin et Pouchet, t. xix., 1883, p. 113).

	Quantity of iron in 1000 parts.
Hens' eggs (without the shell)...	0.00570
Snails .....	0.00360
Beef bones.....	0.01200
Sheep's foot.....	0.02090
Wheat bread.....	0.00480
White beans.....	0.00740
Oats.....	0.01310
Lentils .....	0.00830
Potatoes.....	0.00160
Cow's milk.....	0.00180
Carrots.....	0.00090
Indian corn.....	0.00360
Rice.....	0.00150
Apples.....	0.00200
Spinach.....	0.00450
Cabbage.....	0.00390
Red wine of Beaujolais.....	0.01090
Beer.....	0.00400
Seine water .....	0.00104

But do not forget that in order that lentil flour may possess all its properties it must be cooked, and it is in this form that you should prescribe it for your patients. It is quite probable that the sweet revalrescière (a patent farinaceous preparation common in France), and which has been so much advertised, is composed in part of malted lentil flour.

By the side of these starchy vegetables, and at their head, should be placed potatoes, an aliment to-day quite as indispensable as bread. You have seen by a foregoing table how small the proportion of starch contained in potatoes, and in this respect this vegetable occupies a low place ; hence the applicability of potatoes to the dietary of diabetes.

The herbaceous vegetables may be divided into three great groups,—vegetables rich in vegetal albumen and in nitrogen, such as cabbages, water-cresses, asparagus, mushrooms, truffles ; then mucilaginous and saline vegetables, such as lettuce and chiccory ; lastly, vegetables rich in acids, such as sorrel and tomatoes. Let us glance over these three groups.

The first comprises those vegetables which are the most nutritious but whose digestion is at the same time the most difficult. Leven maintains that cabbage is very hurtful to the stomach. I cannot agree with him, and regard cabbage as an excellent aliment, highly azotized, which is well digested when sufficiently cooked.

I will say a few words about mushrooms. Despite the large quantity of water which enters into their composition,—eighty-five to ninety per cent.,—they contain considerable nitrogen, and for this reason are nutritious. Carl Wœrner, of Upsal, who has recently studied the alimentary value of mushrooms,

has shown that a kilogramme of beef has for equivalent :

	Kilogrammes.
In edible mushrooms ( <i>Agaricus esculentus</i> ).....	9.30
In oyster mushroom ( <i>Agaricus ostreatus</i> ) .....	10.60
In morilla ( <i>Morchella esculenta</i> ).....	15.20
In chanterelle mushrooms ( <i>Chanterellus cibarius</i> )	41.60

The second class contains the mucilaginous and saline vegetables, and includes chicory, lettuce, spinach, artichokes, celery, string-beans, asparagus, green peas, carrots, beets, and pumpkins. These are the aqueous vegetables, and the quantity of water which most of them contain is represented in the following formula :

	Per cent.
Cucumbers.....	96.2
Asparagus.....	92.2
Spinach.....	91.7
Cabbage.....	87.7
Turnips.....	87.0
Carrots.....	87.5
Turnip-cabbages.....	82.0
Artichokes.....	76.0
Jerusalem artichokes.....	76.0

Certain of these vegetables contain also inosite or sugar, as the beet and carrot ; the greater number are rich in salts, such as malates and oxalates of lime or potassium. This richness of vegetables in potassium is one of the most interesting points connected with their composition, and shows their utility in nutrition. Boussingault has given a good analysis of vegetables with respect to the quantity of potassium which enters into their composition. One kilogramme of the following vegetables contains the amount of potassium here given :

	Grammes.
Cabbage.....	2.6
Chicory.....	1.7
Turnips.....	3.7
Carrots.....	2.5
Beets.....	6.8
Potatoes.....	3.2
Spinach.....	4.5

Hence Beunge has insisted on the necessity of introducing into the dietary of individuals who subsist largely on vegetables common salt, in order to maintain a constant equilibrium between the salts of potassium and sodium, an equilibrium which is essential to a healthy nutrition.

The last group is constituted by vegetables rich in acid, and particularly in oxalic acid. We have here sorrel and the tomato, which, when eaten too freely, may give rise to oxaluria. There has been much discussion respecting this physiological oxaluria, some pretending that it may be brought about in-

dependently of alimentation, others that it is always of alimentary origin. While believing that the latter view is the correct one, I shall reserve what I have to say on this subject till I come to speak of the diet of urinary gravel, and in particular of oxalic acid gravel. It remains to finish what pertains to vegetable foods by speaking of fruits.

Fruits complete the alimentation of man by the acids, the salts, and the sugar which they contain. Their general composition is very complex ; besides sugar, salts, and acids, gum, cellulose, and a small proportion of azotized matter enter into their composition. The following is Berard's analysis :

#### ANALYSIS OF RIPE FRUITS (BERARD, 1821).

	Apricots.	Peaches.	Pears.	Cherries.	Prunes.
Azotized matters.	0.17	0.93	0.21	0.57	0.28
Coloring matters.	0.10	.....	0.01	.. ..	0.08
	(Yellow.)		(Green.)		(Green.)
Cellulose.....	1.86	1.21	2.19	1.12	1.11
Gum.....	5.12	4.85	2.07	3.23	2.06
Sugar.....	16.48	11.61	11.58	18.12	24.81
Malic acid.....	1.80	1.10	0.08	2.01	0.56
Lime.....	Traces.	0.06	0.04	0.10	Traces.
Water.....	74.47	80.24	83.88	74.85	71.10
	100.00	100.00	100.00	100.00	100.00

The acids contained in fruits are very variable. Thus, peaches, apricots, apples, pears, and currants contain malic acid ; grapes, tartaric acid ; oranges and lemons, citric acid ; quinces, pectic acid ; the latter, by undergoing transformation into pectine, enables us to make jelly of this fruit.

Like vegetables, fruits introduce into the economy alkaline principles, such as lime and potassium ; they are then useful foods. By the sugar which they contain they serve also for nutrition, but when eaten too freely they become purgative.

I ought especially to call your attention to grapes, from which therapeutics has derived such great advantage in the treatment of certain affections,—a kind of treatment known under the name of *grape-cure*. Very much in vogue in certain parts of Switzerland and Germany, and now employed in France, this mode of treatment is particularly applicable to gastro-intestinal affections. It has proved of service in abdominal plethora, and paretic conditions of the alimentary canal from high living or overeating. If we may trust Carrière and Curchod, the grape-cure is also an efficacious means for combating diarrhoeic fluxes and certain diathetic states, as gout.\*

These are the principal rules to follow.

\* Carrière, *Grape-Cure in Switzerland in the Treatment of Chronic Diseases*; Curchod, *Theoretical and Practical Treatise on Grape-Cure*. Vevay, 1860.

You will direct the patient to eat before his meals a certain quantity of grapes, which he must himself gather from the vines, and which should be eaten while being gathered. I say a certain quantity, for it is impossible to say exactly how much each patient should eat. He ought, however, to eat to complete satiety, for the benefit is largely due to an excess being ingested. As for the kind of grapes to choose, the best is the white grape, with fine skin and delicate pulp. The skins must, of course, be rejected, and the seeds, if possible. As is the case with the whey-cure system, there are two important factors in the causation of the good results obtained from the grape-cure. The fruit itself by the saline elements which it introduces acts favorably on the surface of the digestive tube, and the sojourn (with active exercise) in the open air has an invigorating effect. It is, in fact, in the midst of the most beautiful scenery of Germany, Switzerland, Silesia, and Tyrol that the grape-cure is carried out. This completes what I have to say about vegetable foods, and I pass on to the consideration of fatty foods.

The fatty aliments consist of butter, fats, and oils. When I was on the subject of primordial alimentary principles, I reminded you of the importance of these fatty aliments in nutrition. Not only do they furnish to the economy the hydro-carbonaceous materials which it needs, but they oppose, in a certain measure, if we may trust the experiments of Debove and Flamant, the destruction of albuminoid elements, so that we may consider them as *sparing* aliments (*aliments d'épargne*). If their nutritive value is great, their digestibility is feeble; hence it is that these fatty foods quite often prove to be the most indigestible, and when eaten in moderation they are a source of irritation and discomfort in the digestive tube, and, if taken in considerable quantity, they become real cathartics, constituting what has been described under the name of oily purgatives.

All these fatty substances are of vegetable or animal origin, constituting the fixed oils or fats. We may even add a third group,—the mineral fatty bodies, such as vaseline, a product of petroleum, and which, by a curious artificial process of refinement (as Riche has lately shown) has become an article of food. It has, however, been shown by experiments on animals that if vaseline be not toxic it does not possess any nutritive properties.

Among these fatty bodies there is one

which plays a considerable rôle in therapeutics. I refer to cod-liver oil. From time immemorial among the maritime populations of the extreme north—in Iceland, in Greenland, in Norway—cod-liver oil has not only formed an important article of food, but has been applied to medical uses, special curative virtues having been attributed to it in rheumatism, neuralgia, and consumption. Percival and Darbey, at the end of the last century, called the attention of physicians to these remedial properties, but it was not till 1822, and consecutive to the work of Schenck, that the employment of this oil became general; and in France its speedy popularity was due to the labors of Bretonneau and Duclos.

To-day everybody is agreed in ascribing to cod-liver oil physiological properties clearly defined, and which consist especially in an increase of the weight of individuals to whom this oil is administered. We have here one of the results, the best demonstrated of late years, as you will see by the monograph of Rendu, of Lyons, which shows that in promoting increase of weight and fattening in the tuberculous, cod-liver oil is vastly superior to arsenic.\*

Since Hoffer, of Lormé, found iodine in cod-liver oil, there has been a disposition to attribute to this metalloid, as well as to the bromine, sulphur, and phosphorus which the oil contains, the curative action which it possesses. I believe that this is a mistake, and I am persuaded that it is for the most part as fatty substances that these oils do good in the treatment of tuberculosis; and if I insist on this point, it is because the attempt has been made to substitute for cod-liver oil certain iodized oils, which are far from having the same effects.

The question has been often asked, What kinds of cod-liver oil are the best? Shall we give the preference to the pale over the brown oils? I do not think that there is now any doubt as to the answer which should be given to this question, and almost everybody is agreed that the pale oils, known as *virgin oils*, are better tolerated by the stomach than the brown oils, and are more palatable, while being of equal therapeutic value.

Moreover, the fabrication of these cod-liver oils has undergone great improvement, and to-day, with the exception of *oleum morrhue* of Berthé, which is still made in Paris, all the

\* Joanny Rendu, Experimental and Comparative Study of Arsenic and Cod-Liver Oil in the Treatment of Pulmonary Phthisis. Lyons, 1878.

other oils are manufactured at the fishing stations in Sweden and Norway. Instead of making use of livers that have undergone partial decomposition, as was the custom formerly, only fresh livers are now used. These are thoroughly heated over a sea-bath and subjected to pressure. It is, then, the fresh virgin oil which you should always prescribe. The following analysis gives you the composition of these different oils :

Cod-liver oil.					
	White.	Amber colored.	Pale yellow.	Brown.	Dark brown.
Oleine.....	988.700	988.675	988.695	987.449	988.957
Margarine...	8.060	8.066	8.089	9.264	8.323
Chlorine.....	1.122	1.122	1.116	1.018	1.005
Iodine.....	0.027	0.327	0.322	0.310	0.201
Bromine.....	0.043	0.043	0.030	0.031	0.016
Sulphur.....	3.201	0.200	0.196	0.196	0.142
Phosphorus..	0.203	0.204	0.200	0.196	0.076
Acids.....	0.000	0.439	0.897	0.924	0.838
Loss.....	1.344	0.924	0.449	0.102	0.437
	1000.000	1000.000	1000.000	1000.000	1000.000

There has been some dispute as to whether it would do to substitute for cod-liver oil oil obtained from other fishes, such as the skate and dog-fish. By referring to the comparative analysis of Delattre, you will see that the oils of the livers of the ray and the dog-fish are almost identical in composition with cod-liver oil :

	Cod-liver oil.	Ray-liver oil.	Dog-fish-liver oil.
Oleine.....	988.700	986.945	987.114
Margarine .....	8.060	11.017	10.121
Chlorine.....	1.222	1.125	1.018
Iodine.....	0.327	0.105	0.345
Bromine .....	0.043	0.039	0.034
Sulphur.....	0.201	0.165	0.160
Phosphorus .....	0.203	0.286	0.206
Loss .....	1.344	0.238	0.942
	1000.000	1000.000	1000.000

I do not propose here to enter into the detail of the administration of cod-liver oil. A multitude of processes have been devised, which belong rather to pharmacy than to dietetics. There are, however, two points pertaining to the latter to which I desire to call your attention.

First, I cannot too much urge the importance of giving cod-liver oil at meal-time, for when mixed with the whole mass of the food, and at the moment of the digestive process, these oils are better supported than when given on an empty stomach. Some have even gone so far as to recommend the incorporation of cod-liver oil with bread, but this combination is far from being palatable, and those who have used it have soon taken a disgust to both cod-liver oil and bread. The

only association which seems to me a happy one is that which consists in the union of cod-liver oil with sardines, the latter oil being used instead of the oil in which sardines are ordinarily preserved.

You know also that the instrument-makers have devised spoons tapering towards the end, which enable you almost to pour the oil into the throats of your patients, and thus avoid the disagreeable taste which cod-liver oil leaves in the buccal cavity. Habit, moreover, has a good deal to do with the repugnance which persons have to taking cod-liver oil, and while the people of the north relish it, the inhabitants of Central Europe find it very disagreeable. But it is a fact that children generally imbibe the oil with willingness, and, when the habit of taking it is formed, with avidity.

I advise you to discard all those pharmaceutical emulsions which have been devised to mask the taste of cod-liver oil. There are two of these mixtures, nevertheless, which deserve to remain, as they associate with the oil principles which are of use in the treatment of scrofula and tuberculosis. I refer to the preparations of oleum morrhue with iodoform and eucalyptol. The first, highly recommended by Fonssagrives, has the following formula :

R Pale ol. morrhue, 100 grms. (fziiiiss.);  
Iodoform, 0.25 grm. (3¼ grs.);  
Essential oil of anise, gtt. x. M.

The preparation with eucalyptol is as follows :

R Pale cod-liver oil, 100 parts;  
Eucalyptol, 1 part. M.

As for the dose of cod-liver oil and the quantity to be administered daily, this is very variable. Jaccoud, who is one of the most strenuous advocates of this remedial agent in the treatment of tuberculosis, has gone as far as 300 grms. (or about 10 ounces) per day. This is very large dosing, and few stomachs can bear anything like this quantity. Generally one is obliged to be satisfied with the moderate dose of a tablespoonful after each meal.

My regretted master, Behier, had an instinctive horror of cod-liver oil, and would never prescribe it; as a substitute, he recommended butter. Butter is, in fact, an excellent aliment, but very inferior as a fatty principle to fish oils.

Butter is constituted, as you know, of those oil-corpuscles which are in suspension in milk.

It contains 83.35 per cent. of pure butter and 16.25 of buttermilk. The composition of butter is very complex. What especially characterizes it is a sweet oil formed of a mixture of oleine and butyrine. Butyrine, in contact with air, undergoes transformation into butyric acid, which gives to rancid butter its disagreeable taste and smell. Bromeis has completed the analysis of Chevreuil, and gives the following as the composition of good butter :

	Per cent.
Margarine.....	68
Butroleine.....	30
Butyrine, caproine, and caprine.....	2

Butter is an excellent fatty aliment, the usage of which you will do well to recommend to feeble and emaciated persons. It enters into several pharmaceutical preparations. It is made the basis of several ophthalmic salves, such as the pomade of Regent, the pomade of Benedict, the pomade of St. André, of Bordeaux. These preparations ought every one of them to be now abandoned, for the tendency of butter to become rancid makes it a bad excipient, and the unalterable mineral fats are far preferable.

Under the name of *bromo-iodized butter*, Trousseau proposed the following mixture, which he designed to replace cod-liver oil :

R Iodide of potassium, 0.05 grm. ;  
 Bromide of potassium, 0.20 grm. ;  
 Chloride of sodium, 2 grms. ;  
 Fresh butter, 125 grms. M.  
 S.—To be spread on bread like butter.

I have, however, very little faith in any of these substitutes for cod-liver oil.

As intermediate between butter and milk should be mentioned cream, which has been vaunted in the treatment of certain consumptive affections and gastro-intestinal disorders. The following is Hasson's analysis of cream :

Butter.....	20	and	sometimes	30	per cent.
Caseine.....	29	"	"	11	" "
Serum.....	51	"	"	59	" "
	100			100	

Cream is, then, a mixture of butter, caseine, and serum. It is easily borne by weak stomachs, and doubtless sometimes renders service where other fats cannot be tolerated.

Such are the different points to which I desired to call your attention *à propos* of vegetable and fatty aliments. Now that you understand their composition, before studying the bases of Dietetics I must speak of Beverages. This I shall do in the next lecture.

## ON THE NURSING AND CARE OF THE INSANE.\*

BY CHARLES K. MILLS, M.D.†

WITH many matters that are sometimes included in the published or oral instructions which are given to nurses and attendants upon the insane, it is not my purpose to deal in the present lecture. In the lectures delivered in the other departments of the Training-School, the surgical and the medical in particular, specific directions have been given with reference to many things necessary to be known by those who are in attendance upon the sick or injured, whether sane or insane, such subjects as, for instance, dislocations and fractures, sprains, wounds, and hemorrhages ; artificial respiration ; sunstroke ; the recognition of different forms of insensibility ; the use of compresses, poultices, stupes, and fomentations ; and the treatment of bed-sores and ulcers.

Little has been published with reference to the nursing and care of the insane, except what may be found under the head of treatment in the general text-books on insanity. Two or three small books have appeared, during the present year, in Great Britain and in this country. One, entitled "A Handbook for the Instruction of the Attendants on the Insane," was prepared by a sub-committee of the British Medico-Psychological Association, appointed at a branch meeting held in Glasgow on February 21, 1884, and has been published in this country by Cupples, Upham & Co., of Boston. It contains much useful information and valuable instruction, but too much attention is devoted to the consideration of elementary anatomy and physiology. A more valuable work is entitled "How to Care for the Insane," by W. D. Granger, M.D., first assistant physician in the Buffalo State Asylum for the Insane, and published by G. P. Putnam Sons, New York and London. I have obtained from both of these books some valuable facts, hints, and suggestions ; but most of my remarks will be based upon observation and experience, and upon information obtained directly from specialists, and from the medical

\* A lecture delivered before the nurses of the Training-School for Nurses of the Philadelphia Hospital, in the Insane Department of the Philadelphia Hospital. This lecture is part of a forthcoming book by Dr. Mills, entitled "How to Nurse and Care for the Nervous and the Insane," to be published by J. B. Lippincott Company.

† Consulting Physician in the Insane Department of the Philadelphia Hospital, etc.

officers and attendants of insane hospitals with which I have been connected as consultant.

While a knowledge of the anatomy and physiology of the nervous system, and the nature of the different forms of insanity, may be of value to nurses and attendants, it is not strictly necessary that they should be fully informed about such subjects. There is, indeed, a certain danger that if too much attention is paid in the instruction of nurses and attendants to branches which belong, in strictness, to a true medical education, they may make the mistake of supposing that they are the doctors. The information absolutely necessary for nurses to have about the structure and functions of the nervous system can be compressed into a very small compass. It is necessary that they should know that the brain, with the details of the treatment of whose diseases they are sometimes intrusted, is an organ, which, although deeply seated within a thick and strong bony chamber, is subject, through the multitude of nerves which put it into communication with the outside world, to impressions which soothe, which annoy, which comfort, which distress, or which irritate.

It is well also that they should have some knowledge as to the forms of insanity and the special symptoms exhibited by certain patients; but, as already intimated, this knowledge need not be very extensive nor profound, but it should be exact as far as it goes. When it is remembered that even educated physicians, unless they have spent some time in the special study of insanity, have considerable difficulty in separating the different forms of insanity, it is easy to see that it would be folly for an individual who is not medically educated to try in a little brief instruction to obtain such information. The superficial features of a case will not enable an opinion to be reached as to its nature. Thus, in melancholia, which is a form of mental disease the essential feature of which is emotional depression, a patient sometimes has the violent outbreaks of agitation or excitement which are really the result of depression; and, conversely, a patient suffering from true mania may, for brief intervals, be in a state of great moodiness and depression. I might illustrate by references to other well-known forms of mental disease. What a nurse should know is that there are certain great divisions of diseases of the mind which give special symptoms, and that patients must be treated in this way or in that, according as they suffer from one or the other of these.

The doctor having once, in the presence of the nurse or attendant, clearly made the diagnosis of the form of mental trouble, the latter, knowing this, should bear certain facts in mind: should remember, for instance, that a case of melancholia is likely to be suicidal or to starve to death; that one of mania is not infrequently destructive or homicidal; that one of monomania may exercise duplicity, and may suppress for a time his delusions; that a dement is apt to be filthy, and not to take care of himself in any way; that an insane epileptic may one minute be peaceful and serene, and the next may be in a most dangerous motor or maniacal paroxysm. To illustrate still further, attendants should know that for various reasons accidents are very likely to occur among cases of parietic dementia,—the “general paretics,” as they are commonly termed in the hospital. These patients,—although often exceedingly weak and frail physically,—owing to their peculiar mental condition, to their delusions of strength and grandeur, are likely to be demonstrative and pugnacious. Frequently they have weak hearts, or degenerated livers or kidneys; often, as in locomotor ataxia,—a disease closely allied in pathology, and often merging into it,—their bones are very brittle; not infrequently they have lung-troubles. If such patients are handled as roughly as a case of ordinary acute mania, the consequences may be serious. Collapse has been known to come on almost instantly in a patient of this kind after a struggle, and in badly-regulated asylums bones are sometimes broken,—these accidents occurring even when no cruelty or unusual violence is intended or attempted. Attendants should remember that, as a rule, these patients are not as strong as their demonstrations cause them to appear. A serious accident, resulting in the death of the patient and the subsequent trial of the attendant on a charge of manslaughter, occurred not long ago in one of our large hospitals, the patient being a general parietic with pugnacious and aggressive symptoms, but with advanced mental and physical degeneration. It is on just such matters as flow out of considerations of this kind that attendants require to be informed; they need that kind of knowledge of mental disease which will enable them to discriminate in their management of patients of different classes.

Dr. Spray says that they should be encouraged to take a scientific interest in their patients; and, properly understood, this assertion is true. I simply do not think that it

will be of any service to the unfortunate patient for them to become sciolists in psychiatry,—that is, to have a smattering of knowledge of the anatomy, physiology, and pathology of insanity to parade on occasions, or to make use of improperly in behalf of the patient; but the kind of scientific knowledge which they should have in order to manage the insane for their best interests is that which comes from a study of the mental, physical, and other qualities of their patients, and of the details of the best methods of handling them morally, mentally, and physically. They should study their patients; they should learn what gives them pleasure or pain: what, in cases of melancholia, will best serve to draw them out of the mental shell into which they have retired; in cases of mania, what will best answer to soothe and calm their stormy minds; what, in case of fixed delusions, will best divert them from the unhealthy channels into which their thoughts are directed.

They should have sufficient knowledge of what is meant by delusions, hallucinations, illusions, etc., to enable them to understand the mental condition of the patient for certain practical purposes which come within their own province. Not a few insane have delusions which they, for a time, or altogether, suppress, or which are not freely or openly expressed. The existence of such delusions in most cases is, indeed must be, known to the physician who has the patient in charge, and the nurse or attendant should be promptly informed, in order not only to guard against special dangers which may arise out of the delusions, but also to be better able to manage the unfortunate patient without offence or injury. An attendant who knows that the patient has delusions which may lead to mutilation will be on guard against the occurrence of mutilation. In one case of which I have knowledge, one of the patient's delusions took the form that it was his duty to destroy his eyes, because they had offended, and he almost succeeded in accomplishing this insane purpose before a new attendant had become properly informed as to the delusion.

Under the influence of peculiar delusions mutilations of a most extraordinary character are sometimes performed, and attendants should therefore always be upon the alert. To no one so much as to the insane does the old saying, that it is the unexpected that always happens, so fully apply. After, seemingly, almost every avenue for the commission of suicide or self-mutilation has been provided against, some new device will be put in action,

and perhaps successfully. I recall one instance of a patient in a large hospital who was noticed speaking in a mumbling manner. He was at first passed by; but, on second thought, was questioned, and, on refusing to open his mouth, it was opened forcibly, and it was found that he had tied his tongue with a cord, which had caused it to be much swollen, and would probably in a short time have brought about sloughing, and possibly fatal hemorrhage. In this case the act was performed in all probability under the influence of a delusion that his tongue was an unruly member. Although not under my charge at the time of the occurrence, this man was at one time a patient of mine, and one of his delusions had reference to his tongue or speech.

It is well that nurses and attendants should know not only that the sane sometimes simulate insanity, but that the *insane* also sometimes simulate insanity, giving a curious combination of real and feigned disease, which is sufficient sometimes to baffle even a skilful expert. It is well that this should be appreciated, because it has happened to me, as well as to other physicians who are concerned with the care and treatment of the insane, that attendants, otherwise faithful and suitable for the work, become disturbed as to the existence of insanity in the patients whom they discover to be shamming in some particulars. They discover some deception, and with their little knowledge begin to think that they have solved the problem of the case better than the doctor himself.

Another similar point, which it is well, perhaps, that attendants should know, is that among the really insane hysteria in some form is often present. We have not only a form of insanity which is called hysterical, but hysteria in many forms manifests itself among the insane of different classes. I am led to remarks like these for practical reasons which have grown out of experience. I have had a faithful nurse come to me and say that a patient was hysterical; that she wished to create a sensation; that she would not hurt herself; and such statements may have had some foundation in truth; but in just such a case as this, also, I have known, within twenty-four hours of the time at which similar statements were made, the patient to almost succeed in committing suicide in a way that left no doubt for a moment even in the mind of the sceptical nurse. A nurse should not have an opinion which she puts in practice to the possible danger or detriment of the patient.

In the long run she will be safest to refer all doubts to the physician rather than to act upon them herself.

Later I will speak of the importance of cleanliness on the part of attendants, and also of the close attention which they should pay to cleanliness on the part of patients. Not only should cleanliness of body be attended to as a matter of great importance, but cleanliness of speech and of heart are essentials for nurses and attendants upon the insane. A vulgar, profane, or immoral person has no right to be in charge of an insane patient.

If I were to be asked who make the best attendants, I should say young men or women, not necessarily overlearned, but bright, intelligent, sympathetic, and sensible persons. At one of the large asylums, in answer to my inquiries, I was told that on the women's side the young, strong Irish girls, on the whole, made the best attendants, for the reasons that, as a rule, they were strong, had good animal spirits, were quick, and, at the same time, were kind-hearted. A good nurse or attendant for the insane should be firm and yet forbearing, should be quick and yet not hasty, should be courageous and yet not aggressive, should have tact and yet not be deceitful. It has often been observed in large institutions for the insane that the coming of a new nurse or set of nurses will change for a time the conduct and character of a whole ward. Order will give place to confusion, and quietness to discord. A nurse who is fussy and too demonstrative is, above all, a nuisance, particularly in public institutions. A nurse should avoid lying to or deceiving the patients under her charge. Just as in the examination of the insane an occasion may arise when a doctor will be justified in resorting to stratagem or even to deception, so it is possible that a nurse or attendant in some grave emergency or peculiar position may be justified in temporarily deceiving a patient. Such occasions are, however, exceedingly rare, and deception should never be practised when it is in any way possible to avoid it. Most insane patients, unless they be demented, are capable of recognizing deceit and dissimulation in others. The tendency of the insane mind itself is often to deceit and dissimulation, and a part of the moral or psychical treatment of the insane should be the enforcement, by example, of good moral principle. Promises which cannot be kept should not be made.

The duties of a faithful nurse or attendant upon the insane are, as a rule, arduous and wearing. Sometimes a nurse may be put in

charge of a private case—one of dementia or mild melancholia, for instance—which will give comparatively little trouble; but, on the whole, cases of insanity require great care and attention, and to be in charge of them is not to have a sinecure. In one of the large State hospitals with which I was formerly connected as consultant, the best and strongest attendants, after a year of faithful service, usually showed marked signs of physical and mental wear. The amount of service required by the regulations of some of the large asylums is, I think, too great, while, as a rule, the compensation is far too small.

The nursing and care of the insane in private practice is a matter of grave importance, and one which requires some special points of consideration. If sufficient means are at hand, some forms of insanity can be as well, or even better, treated at their own homes or in private houses than in hospitals or asylums, either private or public. Some forms of mental disorder are comparatively easy to manage at their own homes. Some, however, present peculiar difficulties. Among the cases most likely to be treated with success at their homes, with ultimate chances of recovery, are mild melancholia, common acute mania, when not too severe in character, and some forms of hysterical insanity. Some other forms of insanity, such as senile and secondary dementia, idiocy and imbecility of various grades, may be cared for at home, as a rule, without danger, although in such cases nothing is to be hoped for, so far as cure is concerned. The effort should never be made to treat patients at home, or in private houses, if such patients require constant watching, unless the friends or relatives of the patient are fully able to employ faithful attendants. The physician is often asked whether such and such members of a family cannot look after the patient. As a rule, but one not without exceptions, it is running a risk to allow a patient who is dangerous to himself or others to be attended solely by members of his family. It certainly cannot be done without great risk, if those who are supposed to have charge of the patient have other work or duties which claim their attention. When patients are so situated financially that attendants cannot be hired, or that members of the family or friends cannot give them exclusive attention, it is far better to resort to hospital or asylum care.

It will frequently happen in the private or home care of the insane that two attendants are put in charge of a patient; occasionally the number will be even greater. In all such

cases, unless the patient simply require one attendant to be in charge absolutely for a certain number of hours and the other for a like time, the physician finds it desirable to have one in chief authority. To one he consigns the chief charge, making him or her responsible to the physician, and requiring the other, when it is necessary, to act under instructions. Occasions arise, particularly in the care of the violent or suicidal insane, when it is necessary for prompt and decided action, such action as can be taken and directed by one clear head. In such a case it should be understood that the requests or even directions of the chief nurse shall be coincided with or obeyed by the other. I have known a patient to be injured, so far as efforts to control her were concerned, by the petty jealousies which have arisen between the nurses in attendance. It has seemed to me—possibly I may be mistaken with reference to this—that these jealousies are more likely to arise among women than among men. No appearance of discord or disagreement between attendants should ever be shown before a patient. Such an exhibition is in some cases destructive of all efforts to control a patient for his or her own good.

Much of the instruction which is given to those who are in charge of the insane, whether resident physician, nurses, or attendants, must necessarily have reference to the conduct, habits, and peculiarities both of patients and those in charge, and it is for this reason that I am compelled to devote so much time to the consideration of questions of this kind.

Attendants should never foolishly ridicule patients. While sometimes harmless amusement may be derived from listening to the vagaries of the insane whose delusions or notions are of a pleasant or joyous type, patients should never either be encouraged in their delusions or ridiculed because of them, or of anything else which is the result of their impaired mental condition.

In institutions nurses and attendants should be careful not to indulge in favoritism, and not to single out any patients for special antipathy. Probably nowhere in the same space can so many annoying, aggravating, and disagreeable individuals be found together as in a large insane hospital. It follows, as a matter of course, from the mental condition of the inmates, that this should be so; but the highest type of nurse or attendant is one who, appreciating all this, is able to pursue a straightforward, honorable, unbiased course in caring for the patient.

All disputes and differences of opinion

should be referred to the physician. The highest tests of the quality of a good attendant in cases of mental disorder are those tests which are exhibited in the personal characteristics of the individual. Forbearance under temptation, the ability to suppress envy, jealousy, or self in every way; the willingness to do and deny all things for the sake of the patient, furnish the best evidences of the needed qualities in such an office. The nurse who is given chief authority in the care of a private patient should not be officious or exacting, but should make it her special aim to see that the directions of the physician are implicitly carried out; should report to the physician in charge everything disagreeable and all derelictions.

In most cases the chief nurse should keep a careful record of the details of treatment, and also of the meals, amount of sleep, exercise, kind of occupation or amusement, etc. A systematic method of recording the time of administration of medicines is also advisable.

Attendants upon the insane should not become to any great extent routinists. They should not become so familiar with their patients as to forget many of the little things that they may need. The insane often suffer for want of little things, of which they need not be deprived, and of which no one cares to deprive them, but which they often do not get because of carelessness or thoughtlessness. They often suffer, for example, for water. I have been told of an intelligent lady who drank her own urine, not because of a delusion, but because of absolute uncontrollable thirst, which was not properly satisfied. Such, probably, is the case in not infrequent instances, although acts of this kind are more frequently, no doubt, due to delusions.

Sometimes the insane do not receive sufficient food. In some forms of insanity, owing to the tremendous waste of tissue which takes place in consequence of the wearing mental disorder, large quantities of food are called for. Of course, arranging of the amount of food is a matter for the physician, but nurses should see to it that the food is given when directed. As a rule, however, the insane eat too much rather than too little, and this, of course, must be guarded against.

The protection of the insane from the commission of suicide is a most important duty upon the part of an attendant. It is strange in how many ways and with how much shrewd-

ness the insane will accomplish this dire purpose if intelligent vigilance is not exercised. Suicides by the insane, like suicides by the sane, are of the most diverse character as far as method is concerned. An insane patient has been known to hang herself by a shoe-string or an apron-string to the door-knob of a room ; or the bed-cords, the sheets, clothing, etc., have been employed. To drown themselves patients do not require rivers nor even bath-tubs. They have been known successfully to accomplish this purpose by thrusting the head into a pail, or even into a basin of water. Sometimes objects are thrust by the patients into their own mouths to choke themselves or strangle themselves to death ; sometimes they cut themselves with glass obtained by breaking windows. Knives, scissors, razors, and all forms of cutting instruments should be carefully kept out of the way. The greatest possible care should be taken with reference to the custody of medicines administered to the patients. Here, again, it is advisable that those in charge should have some little practical instruction as to the strength and danger of the most potent remedies which are intrusted to their care for administration. They cannot be expected to have profound and exact knowledge as to the physiological properties, sources, etc., of morphine, conium, hydrobromate of hyoscyne, atropine, duboisia, digitalis, chloral, cannabis indica, and the long list of powerful medicinal implements which are put into their hands ; but they should know that these drugs are dangerous and deadly poison in more than a proper dose, and they should keep them out of the reach of patients in the intervals between the times of giving the doses ordered. Where possible, it is well to keep them in an adjoining room, and always under lock and key, and entirely out of reach. While, however, in the case of patients suicidally inclined, the means of suicide should be kept or put out of reach, this should not be done in a fussy or demonstrative way.

Comparatively little restraint of a mechanical kind is now used in the care of the insane. In some cases, however, rare though they be, it may be absolutely necessary to protect patients from mutilation or suicide. Mechanical restraint should not be applied by an attendant except by the direction of a physician, and, if it is used, the greatest possible care should be taken that no evil consequences result. Not long since, in a large hospital for the insane, a patient, who had been restrained by straps or cords in a bed, so dragged himself down over the side of the bed as to ac-

ually cause his death by dragging on the bands.

When it becomes absolutely necessary to take hold of an insane patient, care should be exercised as to the manner in which it is done. Usually, patients requiring to be taken hold of are violent,—cases of mania, homicidal monomania, of agitated melancholia, and the like. When two attendants are present, it is well, while one secures the attention of the patient by demonstrations in front, for the other to get behind the patient, and either throw the arms around or seize both arms carefully but firmly above the elbows. Whatever plan of seizing patients is accomplished, great care should be taken not to inflict any injury. It is only in self-defence, in defence of life or limb in a great emergency, that an attendant is ever justified in roughly handling a patient. A patient, of course, may kick backwards when seized from behind, but the attendant, by slipping his feet and legs as far as possible to one side, can usually avoid being injured in this way.

When applications of heat or cold are made to the insane, special attention should be paid to them. In some forms of insanity great insensibility of the skin is present, and patients would in these cases allow blisters, mustard-plasters, stupes or fomentations, or any form of hot or counter-irritating applications to remain until serious blistering occurred. On the other hand, such patients are sometimes more impatient of such applications than the sane. The same remarks apply to the use of cold water or ice.

All physicians who are engaged in the care and treatment of the insane now recognize the importance of occupation, amusement, and educational training as therapeutic resources. To attendants the carrying out of plans of occupation, amusement, and teaching must be largely intrusted. In institutions, methods and measures for occupation, amusement, and teaching will be carefully planned and regulated if the institutions are up to the times in their management. The great curse of many institutions for the insane has been idleness. It is not within my design in the present lecture to go into the consideration of the methods and forms of employment, amusement, and instruction, but simply to give a few hints and suggestions as to the manner of carrying out the details, so far as these are in the hands of nurses and attendants.

Patients should be encouraged, and in some cases be compelled, to do that work which is called for in their own personal care. They

can be encouraged or made to take care of themselves, so far as cleanliness is concerned. Female patients should be made, when possible, to care for their own rooms, beds, etc., although attention should be paid, of course, particularly in private practice, to the question of the usual customs and habits of the patient.

No matter what may be the work at which an insane patient is engaged, whether sewing, knitting, quilting, ironing, or book-keeping, or, if a man, gardening, ploughing, brush-making, chair-making, or printing, a duty that will be incumbent upon the attendant more often than upon the physician will be to see that the patient does not overwork himself. While on the whole the tendency will be to do too little rather than too much, in some cases insane patients will rapidly and certainly overwork themselves. This is particularly the case in some forms of insanity attended with excitement, some varieties of mania, for instance, in which the patient tends to do everything to excess. Again, a patient may overwork as the result of some special delusion. Dr. Massey speaks of the case of a lady in good circumstances who, having been left with a family to support, resorted to dressmaking, but became insane and was sent to an asylum, where she was induced to go to work in the sewing-room. The result was the production of a new delusion: she believed she was in charge of the sewing-room, with large wages, and made great exertions in consequence. Becoming troublesome, she was transferred to the laundry, where the same thing was reenacted, resulting at last in complete exhaustion and confinement to bed.\*

Exercise is of the utmost importance to many insane patients. In suitable weather, out-of-door exercise should be secured. Here, again, the careful attendant will guard against the patient under-exercising on the one hand or over-exercising on the other.

Torpor of the bowels and obstinate constipation are of such frequent occurrence among the insane that both resident physicians and attendants should have their attention particularly directed to their management. In cases of melancholia, the bowels may remain constipated for days and even weeks, if the patients are neglected. A large number of insane patients in asylums, particularly many of the cases of dementia, are troubled with involuntary evacuations from the bowels or bladder, particularly at night. In private patients the same difficulty may be encountered, and it is

well for physicians and nurses to have some plan of meeting the difficulty. In one large hospital the plan adopted is a very sensible one. The physician in charge has a list of all patients who are troubled in this way, and in the evenings, before retiring, injections of warm water are given. The lower bowel is thus emptied, and a probability is that the patients will not soil their beds.

Cleanliness on the part of a nurse or attendant upon the insane is of the utmost importance. It is important not only for itself, but for the example which it sets to the patient. The insane may be made more filthy than their mental affliction would lead them to be by the example set to them by others; on the other hand, they may become cleanly in habit simply from a good example steadily set.

The bathing of insane patients is a matter of great importance both from the point of view of cleanliness and as a therapeutic agent, and attendants should be thoroughly instructed with reference to this matter. They should also have a lively appreciation of the dangers which may attend bathing. Only the other day a terrible accident occurred in one of the large asylums of a neighboring State, the patient having been literally parboiled by an attendant. As many insane patients make a great fuss and offer much resistance to bathing at all times, a careless or impatient attendant might fail to listen or assure himself of the conditions. Rigid rules are prescribed in all well-regulated public institutions. The rules for bathing which are in force at the State Hospital for the Insane, Norristown, Pennsylvania, so fully express what should be said with reference to this matter, that I will quote the most important of them:

The ward captains will personally supervise the bathing of patients, which shall not be conducted during their absence without permission.

Every patient is to be bathed immediately after admission, and once a week afterwards, unless excused by medical order. Should there be the least doubt as to the advisability of bathing any patient, owing to sickness, feebleness, or excitement, the matter should be immediately reported to the medical officer.

To provide against catching cold, the captains will see that the bath- and dressing-rooms are sufficiently warmed at bathing times; otherwise, to postpone bathing until the rooms are heated.

Any marks, bruises, wounds, sores, pain, or evidence of disease complained of by the patient, or noticed during any of the bathing operations, must be immediately reported to the physician.

During the use of the bath the room is never to be left by the attendant, except by special permission of the resident physician. When the room is not in use the door must be kept locked.

\* *Penn Monthly*, 1879.

Before putting the patient into the bath observe that the water is of proper temperature. It should not be less than 88° nor above 98°.

Never turn on the hot water when the patient is in the tub.

In the bath the body of the patient is to be well cleansed with soap, and in washing the hair be careful that no soap gets into the patients' eyes. After leaving the water especial care must be taken to thoroughly dry the patients and clothe them as rapidly as possible. A separate towel must be provided for every one.

Under no pretence whatever is a patient's head to be put under water.

An attendant must not attempt under any circumstances to bathe a struggling patient alone.

Cold baths must never be given.

Neither before nor after the bath will patients be allowed to stand about unclothed.

The keys are never to be left on the bath-taps, nor are they to be used by the patients.

In conclusion, I will speak briefly of the methods of feeding patients forcibly. I do this because my remarks are intended for the instruction of resident physicians as well as of nurses and attendants. I do not believe that the latter should be allowed to have the feeding of patients in this manner under their own charge, but, as it is necessary for them to assist in performing this work, they should receive instruction as to the whole process in order that they may be better able to render assistance to the physician. In some institutions head-nurses have been allowed to administer food in this way, but it is contrary to the regulations of most institutions for the insane.

Not a few cases of insanity require at times to be fed by force. The cases in which such treatment is called for differ somewhat. In melancholia, patients will allow themselves to rapidly run down in health, or even starve to death, if the food is not promptly administered by artificial means. Sometimes cases of mania will refuse to take food, either because of their general excitement and combativeness or because of delusions. Paranoiacs or monomaniacs refuse food, if at all, because of some fixed delusion. A case of chronic alcoholic insanity, or even, in rare instances, a paretic dement, may refuse food because of a delusion, one, for instance, that the food is being poisoned by physicians, attendants, or others, or that it is a means resorted to to accomplish some purpose on the part of a persecutor. The refusal of food by the case of hysterical insanity, like the apparent attempts at suicide, is usually simply put on or resorted to for the purpose of exciting sympathy. In most cases these patients will obtain food on the sly if possible, but sometimes they will carry on the

deception sufficiently long to injure themselves if the attendants do not resort to active interference.

Various plans of feeding patients by force have been recommended at different times,—two of these are now almost universally employed; and one of the two, namely, nasal feeding, is now coming more and more into general use.

One plan is that of holding the nostrils closed and opening the mouth, or thus compelling it to be opened, while the food is quickly poured into the mouth and the patient is forced to instantaneously swallow it. A certain amount of danger accompanies this plan, which, by the way, is the one often resorted to for recalcitrant children. If any one of you should try the experiment of swallowing liquids or solids while the nose is tightly held so that no air can enter through it, he will find that it is a very difficult or almost impossible thing to accomplish. The very fact that a patient or individual whose nose is held opens the mouth in order to breathe shows the source of possible danger, which is, that the glottis being open to receive air into the lungs at the same moment that food is hastily thrust into the mouth, some of the food is likely to find its way into the wind-pipe and thus choke or strangle or partially choke or strangle the patient. This method of feeding is now not much employed.

Dr. D. Anderson Moxey\* was among the first to call attention to the administration of food and medicine by the nose when they could not be given by the mouth. He resorted to this method in cases of insanity, inflamed and ulcerated sore throat, in glossitis, in deep intoxication, and in infancy, where nothing could be administered by the mouth or retained by the rectum. In his cases of insanity he fed his patients, without the use of a tube, by simply holding a small wedgwood funnel in one of the nostrils, and pouring through it the liquid or semi-solid nourishment. His method with insane patients is described as follows: After first trying to induce the patient to take the nourishment quietly and in the ordinary way, he summoned three attendants at least (four or five if they could be had), and laid the patient down on his back as quietly as possible on a low couch in the middle of the room. If there were only three attendants, one controlled the legs and the other two the arms. If a fourth was present, he attended only to the head, which was

\* *The Lancet*, March 20, 1869.

held between his knees as the attendant sat on a low stool at the top of the couch. If a fifth was present, he assisted in holding down the legs. In this way the patient was completely controlled, and sometimes would yield and swallow in the usual way. Then introducing the end of the funnel gently into one of the nostrils, he poured the liquid slowly into it, pausing now and then to allow the patient to take a deep inspiration, and not allowing the food to accumulate in the funnel. A determined patient would generally be able to sputter a little of it out of his mouth. When such was the case, he poured the contents of the jug faster into the funnel, and sometimes obstructed the other nostril. In troublesome cases a medical man ought, he insisted, to invariably administer the draught, as he could alone properly judge of the extent to which it was necessary to interrupt nasal respiration. Dr. Moxey never found any serious results from this method of feeding. I have referred to these observations of Dr. Moxey to show the perfect feasibility of nasal feeding, and one of the methods of holding the patient, and that the feeding can even be accomplished without the aid of a tube, although undoubtedly this is the neater and better method.

A good tube for feeding by the nose can be made by attaching a soft Nélaton catheter to a long piece of drainage-tube of a calibre which will just allow the catheter to tightly fit into it. To the extremity of the drainage-tube a funnel of large size should be attached.

In nasal feeding some of the difficulties and dangers which are met with should be borne in mind. The number of patients who cannot be fed by the nose is very small. Occasionally, however, a patient is found whom it seems impossible to feed in this way, owing to the choking or strangling produced. This may be because of some peculiar anatomical conformation, or some special nervous idiosyncrasy on the part of the patient. The patients I refer to will choke or strangle with nasal feeding when they will not when the stomach-tube is resorted to. If, when the attempt is made to pass the well-oiled tube through the nostril, resistance is encountered, and if, after a few trials, the tube cannot be made to pass, great force should not be employed by the operator, but at once the tube should be withdrawn, and the effort made to pass it through the other nostril. In nearly all cases where special resistance is offered on one side, the tube will pass with ease upon

the other; and this in most instances is because, if hypertrophies or projections exist upon one side, there will be upon the other corresponding or compensating depressions. Sometimes, but rarely, the mucous membrane is exceedingly irritable. After the nasal tube has passed through the nostrils, it seems to have a peculiar tendency in some cases to drop into the glottis, the patient struggling and attempting to scream meanwhile. Some patients will spit or force the tube out into the mouth, and attendants can, sometimes, through the mouth, keep the tube, which has been passed through the nose, in position. Occasionally the nose is made sore by the use of the tube, but this is not likely to occur if the tube is always perfectly cleaned and well oiled. If it is of the proper kind,—that is, a soft tube,—there will be no danger of injuring the parts by breaking or perforating the mucous membrane. Indeed, one of the advantages of the nasal tube over the form of stomach-tube, or œsophageal tube, that is commonly employed, is that the danger of injury by perforation or abrasion is much less. The stomach-tube must be a little larger and of firmer make, and is likely, after a little usage, particularly if not looked after with great care, to become stiff and hard. I have heard of one instance in which the œsophagus was pierced by a stomach-tube in the hands of an unskilful attendant. In using the nasal tube great care should always be exercised to see that at least fourteen to sixteen inches of the tube have been passed before beginning the feeding. This will make it certain that the entrance to the wind-pipe has been passed. Of course care should be taken to observe that the tube has not doubled on itself, but this will not be likely to occur, or to be overlooked if it does occur.

"Whether fed with the funnel or the stomach-pump, the patient should sit up, and, if he is very obstructive, a restraining-chair will save the patient much needless muscular exertion, the physician much trouble, and diminish the chances of doing an injury. In case the œsophageal tube is passed along the floor of the nasal cavity, it is apt to encounter a resistance, and be deflected forward by a prominence which is sometimes very marked on the posterior pharyngeal wall, and which corresponds to the bodies of the cervical vertebræ. Dr. Tukey advises throwing the head of the patient back at the moment when the sound approaches the posterior nares, the tube having previously been bent a little, so as to facilitate its downward passage; then, at the

moment when it is about to glide down into the œsophagus, when there is a risk of its passing into the larynx, he advises the head to be brought forwards and downwards, so as to send the point against the posterior wall of the pharynx. After passing the upper end of the œsophagus, the tube is usually swallowed, as it were, and glides down without any further difficulty into the stomach through the action of the constrictor muscles."\*

Whenever a patient is fed forcibly, care should be taken to have ample force to restrain him without violent struggle. The sight of overwhelming force will have a good moral or psychical influence over the patient. Three persons can feed a patient successfully, no matter how great the inclination to resist, if these persons are skilful and have sufficient strength. With less than three persons the difficulty will be very great, and in some cases it will be impossible successfully to accomplish the purpose. One attendant should always be charged with the task of firmly holding the head in position; another can hold the arms and hands, with the body thrown over the limbs of the patient,—before this is attempted the patient having been well enveloped in a blanket or sheet. It is better, however, to have two attendants hold the arms and legs of the patient.

After a patient has been fed the tube should be always promptly cleansed. An attendant who does not attend to this matter is derelict in duty. Hot water cannot be used because of the melting of the india-rubber, but the tubes should be washed by allowing cold water to run through them and be passed over them. Negligent attendants are likely to neglect this matter.

Whether fed by the mouth and œsophagus or through the nose, in rare instances, patients learn to vomit or regurgitate the food. If this occur, it is a matter for a physician rather than for a nurse or attendant. It has been found that the administration of morphine and hyoscyamine prior to the time of feeding will prevent the patient from exercising this power.

If the nasal mucous membrane or the mucous membrane of the throat should be unusually irritable, resort may be had to a weak solution of the hydrochlorate of cocaine, which can be painted over the mucous membrane of the nose or throat in those cases in which it could be done without too great effort.

\* Insanity, its Classification, Diagnosis, and Treatment. By E. C. Spitzka, M.D.

# A CONTRIBUTION TO OUR KNOWLEDGE OF FEVER, AND THE AGENTS WHICH PRODUCE OR ARREST IT.

BY DRS. H. C. WOOD, E. T. REICHERT, AND HOBART A. HARK.

(Continued from page 583.)

## PART II.—PYREXIA.

THE fever produced by pepsin is so marked that we have been led to study closely the phenomena produced by these injections, thinking that they might throw some light upon the pathology of the febrile process. The first series of experiments were directed to determining whether the relations between the temperature of the body, the state of the pulse, and the respiration are in any way fixed or definite.

These experiments are as follows:

*Experiment 20.*—Dog; weight, 24 pounds. Hance Bros. & White's concentrated pepsin.

Time.	Press.	Pulse.	Resp.	Temp.	Remarks.
2.55	160	138	15	103.5°	
2.56	.....	.....	...	.....	Slowly injected 2 grammes intravenously.
2.57.40	90	144	13	.....	
2.58	80	132	...	103.5°	
3.01	140	108	20	103.7°	
3.06	142	180	24	103.7°	
3.11	140	?	36	103.8°	Respirations deep.
3.15	89	.....	...	103.8°	
3.20	50	156	23	103.5°	
3.22	52	.....	18	103.45°	At 3.26 animal died of heart failure.

EXPERIMENT 20.

*Experiment 21.* Dog, weight, 16 5 pounds.

Time.	Press.	Pulse	Resp	Temp	Remarks
2.52	150	132	4	103.5°	In ected in next 45 seconds 1.65 grms. of Hance Bros. & White's concentrated pepsin
2.53	80	204	.	103.3°	
2.55	50	196	.	103.4°	
2.57	44	150	15	103.5°	
3.03	30	180	...	103.6°	

Time.	Press.	Pulse.	Resp.	Temp.	Remarks.
3.07	30	.....	...	103.9°	
3.15	44	.....	...	103.5°	
3.21	75	156	16	103°	
3.28	90	144	16	102.8°	
3.38	80	144	20	102.1°	
3.55	90	192	18	101.7°	
4.10	78	216	16	102°	
4.40	45	216	18	102.2°	
5.20	62	240	40	101.9°	Dog dies within 12 hours.

It will be seen in these two experiments that the pulse-rate was very distinctly increased, whilst the arterial pressure steadily fell, and the temperature either fell or was but slightly affected. The respirations were increased. In order to show to the eye the relations between these alterations, the curves have been prepared. In these the line P represents the pressure, the line T the temperature.

These curves certainly demonstrate that, after injections of pepsin, which either depress or do not affect the bodily temperature, there is no close relation between alterations in the general circulation and the bodily temperature.

The next two experiments were so made as to produce fever. They are as follows :

Experiment 22.—Dog.

Time.	Press.	Pulse.	Temp.	Remarks	<i>Experiment 23.—Dog ; weight, 12 5 pounds.</i>				
3.01	160	156	104.7°	Slowly injected 1 gramme of concentrated pepsin.	Time.	Press.	Pulse.	Temp.	Remarks.
3.05	75	216	104.8°		3.09	140	144	102.8°	Injected slowly 0.63 gramme
3.13	60	216	105.2°		3.10 30	40	132	102.7°	
3.30	120	180	104.2°		3.17	135	108	102.3°	
3.45	122	168	103.8°		3.26	142	120	102.3°	
4.10	120	170	103.5°		3.30	150	132	102.9°	Very decided tremors for some minutes.
4.19	.....	.....	.....	Slowly injected 0.75 gramme.	3.40	140	132	103.4°	Tremors cease.
4.45	95	216	105.1°		3.50	136	156	103.6°	
5.00	115	220	104.6°		4.10	138	168	103.6°	
5.20	120	218	105°		4.20	133	156	104.0°	
5.40	135	240	105.7°		4.25	130	156	103.9°	Vomiting.
5.55	140	192	106°	Bled about 2 ounces.	4.30	130	168	104.1°	
6.00	70	252	106.7°		4.50	130	168	104.2°	Dog killed.
6.10	70	250	107.6°						
6.20	75	288	107.3°	Dog killed.					

EXPERIMENT 23

Unfortunately, in these experiments we failed to note the respirations; but, as with the previous experiment, the pulse-rate rose and the arterial pressure fell, and yet the temperature rose. In Experiment 22 the rise of temperature, considering the animal employed, was very decided.

The following curve expresses the results obtained in an experiment (Experiment 24), whose detail we do not give.

In order to show more clearly the total lack of connection between the circulation and the temperature in ordinary cases of

fever, we here insert some experiments which we have made with antipyretics, especially with the drug antipyrin. In three or four experiments upon uninjured normal dogs we have found that this drug sometimes notably depresses the temperature even when given in doses not distinctly toxic. We now give the records of three experiments so made as to show simultaneously the influence of antipyrin upon animal temperature and upon arterial pressure, two of the experiments being upon normal animals and one upon an animal having a pepsin fever.

EXPERIMENT 24

*Experiment 25.—Antipyrin alone.* Weight of dog, 6 pounds. No pepsin given. Effects of antipyrin on normal temperature and blood-pressure.

Time.	Drug.	Press.	Pulse.	Temp.	Remarks.
2.35		194	104.5°		
2.40		170-194			
2.45	5 grms.	180

Dog struggling violently ever since injection.

Comparing these three experiments with those previously given, the conclusion is inevitable that the temperature of the animal, after the injection of the pepsin, is indepen-

dent of pulse-rate, the arterial pressure, and the rapidity of the respirations.

As a further proof of this entire independence of the blood-pressure and the temperature we give the above tracing. The temperature in a dog (Experiment 28) had been elevated to 107.7° F., at which time the arterial pressure was 170; antipyrin was injected into the jugular vein, and the motion of the kymographion arrested for forty-five minutes, at the end of which time the temperature had fallen to 102.3° F. nevertheless, the blood pressure stood at 164, almost where it had been before the falling of the bodily temperature.

The next step in the investigation was to determine the course of heat production and heat dissipation. A series of experiments were performed with a calorimeter similar to that used by Dr H C Wood in his researches on fever. It does not seem necessary to encumber the present article with the details of

these experiments, but the results obtained are given in the following records, the calculations all being made according to the method of the above investigator.

*Experiment 29.*—A fat pup; weight, 19.5 pounds.

It has occurred to us that the results of these experiments might graphically be represented, and their lessons thereby be conveyed more forcibly to the mind. If on paper ruled horizontally with equally distant lines the space between the lines be considered to represent one degree of bodily temperature, then, so far as heat production and heat dissipation are concerned, such space will represent the number of heat units required to raise the body of the animal one degree of temperature: thus, suppose in a ruled sheet the successive distances between the lines A, A', A'', represent 1° F. for an animal weighing six and a half pounds, and having a specific heat of 0.75, then the value of the spaces between A, A', A'', will each be five units of heat.

If across the horizontal lines in such a plate a series of vertical lines be projected at intervals, and taken to represent each hour of the experiment, it is easy to construct three curves,—one of bodily temperature, one of heat dissipation, and one of heat production. If such curves be correct, the one representing temperature should be exactly related to the others.\*

This relation should be, that when the temperature rises, the hourly increase of heat production added to the hourly decrease of heat dissipation and multiplied by the number of hours should give the height of the temperature curve. Perhaps this may be more clearly expressed algebraically. Let  $t$  represent the height of the temperature curve,  $ip$  hourly increase of heat production,  $id$  hourly

\* In practice, for convenience' sake in making these curves strict accuracy has been by us abandoned. The weights of the various animals are such that only occasionally does the space between the lines represent an even number of heat units, and we have found it better to consider them to represent the nearest even number than to retain the fractions. The departure from accuracy is not sufficient to affect perceptibly the general relations of the curves, but comes out when accurate measurements are made.

Experiments.	Time.	Weight.	Drug.	Temperature.	Hourly dissipation of heat.				Hourly production of heat.				Remarks.		
					Normal.	After Injection.	Increase.	Decrease.	Percentage of decrease.	Normal.	After Injection.	Increase.		Decrease.	Percentage of decrease.
29	8.40 to 10.40 A.M. (2 hours). 12.15 to 2.15 P.M. (2 hours). 2.30 to 4.30 P.M. decrease of heat dissipation; then, for an experiment lasting two hours,

$$t = 2 (ip + dd).$$

because the hourly increment of temperature must be the gain of heat production plus the loss of heat dissipation. If it so happen that heat dissipation is increased instead of decreased, then such increase must be subtracted from the increase of heat production, and the formula becomes (*id* being taken as the symbol for increased dissipation)  $t = 2 (ip - id)$ . If the temperature of an animal falls during an experiment, such fall can only be due to increase in dissipation, or lessening in heat production, or to a combination of these changes. Of course, bodily temperature might fall when there was an absolute increase of heat production, provided such increase was overcome by a greater increase of heat dissipation. Taking  $t$  as fall of bodily temperature,  $dp$  as decreased heat production per hour, express the height of a curve of two hours,  $t = 2 (dp + id)$  or  $t = 2 (id - ip)$  or  $t = 2 (dp + dd)$ .

In applying these equations to test the accompanying curves, it must be remembered that the equations are based upon the suppositions that immediately before the occurrence of the changes of temperature under consideration the heat production and heat dissipation were so balanced that the temperature of the body was at rest.

If, in any experiment, the bodily temperature was falling or rising before the change of temperature under discussion, then allowance must be made for such previous inequality.

In examining these curves, or the results as given in the tables, the most prominent fact, the one which naturally first attracts attention, is that there is no fixed relation between the temperature of the body and the rate either of heat production or heat dissipation, or, in other words, that fever may exist with a lessened heat production, and that the bodily temperature is decided by the relation between the two functions of heat production and heat dissipation.

In all of the experiments in which there was a decided fever, during the coming on of that fever—*i.e.*, in the earlier hours of the paroxysm—heat production was increased, whilst heat dissipation was lessened. Another point worthy of notice is that in Experiment 30 the injection of pepsin was followed by a persistent fall of temperature, which was produced by a conjoined decrease of heat production and increase of heat dissipation.

This phenomenon shows most clearly the derangement of the relations of heat dissipation and heat production produced by pyrogenic agents, for in health decreased heat production provokes decreased heat dissipation, and *vice versa*.

In Experiment 31 the access of fever was preceded by a decided fall of temperature, which fall was caused by an increase of heat dissipation and lessening of heat production.

There was a distinct defervescence in only three of these experiments. In Experiment 29 it was caused by an enormous fall in the rate of heat production. In Experiment 32 it was the result of a consentaneous increase of heat dissipation and decrease of heat production. In Experiment 34, as in Experiment 29, it was due to excessively decreased heat production.\*

These experiments would seem to show that in the course of a febrile paroxysm of sudden acute fever preceded by a fall of temperature and lasting but a few hours, there is primarily an increase of heat dissipation and a lessening of heat production; that during the subsequent rise of temperature there is an increase of heat production and a decrease of heat dissipation until the maximum temperature or near it is reached, and then for a time these functions are variously performed, the relations between them being, however, such as to maintain the bodily temperature; and finally, that when sudden rapid defervescence occurs, it is usually chiefly due to a fall in the heat production, although sometimes heat dissipation is also increased. The curves of a typical acute paroxysm of fever would therefore be something like the following.

An examination of the various curves which we have given will, according to our thinking, demonstrate the correctness of the view that fever is of nervous origin. As fever is accompanied by increased production of animal heat, the pyrogenic agent of the pepsin solution could act in producing the fever only in one of three ways,—either by causing nutritive changes in the blood so rapid as to increase distinctly the production of animal heat, or by provoking similar chemical reactions in the solid tissues themselves through an influence exerted directly upon the tissues, or by affecting the nerve-centres, and thereby influencing the chemical movement of the tissues, either directly or through the medium of

\* The smallness of the figures involved is due to the very small size of the dog.

the circulation. The functions of heat production and heat dissipation in the normal organism are so closely related, one to the other, that any alteration of one is followed by a compensating alteration of the other. If heat dissipation be increased heat production is also increased to make good the loss, but if heat dissipation be decreased heat production is decreased; and, on the other hand, when heat production is increased heat dissipation is also increased, and *vice versa*. In this way the bodily temperature is in health maintained at a steady level. It is not conceivable that a substance which acts simply upon the blood, or the tissues directly, should, by virtue of such action, alter the normal relations between heat dissipation and heat production. Therefore, if by a direct action upon blood or upon the solid tissues an excess of heat production is caused, such excess should be accompanied by a rise of the dissipation of heat, and the elevation of temperature could only

be produced by the increase of the heat dissipation not being able to keep pace with the increase of heat production. It will be seen, however, in looking at our curves, that the normal relations between heat dissipation and heat production are often reversed under the influence of the pepsin pyrogenic agent, so that, on the one hand, when in the beginning of the paroxysm heat production falls, heat dissipation is increased; and, on the other hand, during the height of the fever, the heat production rises, while the heat dissipation falls. This, we believe, proves that the fever is the result of a disturbance of the nervous system. Further, the various experiments which we have detailed prove that the fever is entirely independent of the arterial pressure, since normal arterial pressure may co-exist with high or low temperature, and there is no corresponding rise or fall of arterial pressure with the variations of the temperature in the febrile state. If the increased

heat production were the result of the dilatation of the capillaries of the muscular system, where most of the heat of the body is believed to be produced, such dilatation would probably affect the general blood-pressure, and we therefore believe that our researches corroborate the theory reached in the work of Dr. H. C. Wood, that there are nerve-centres which are directly concerned in the thermogenic functions, and which affect the production of animal heat, independently of the circulation, by a direct action upon the tissues.

(To be continued.)

#### "PASTEURIZATION" FOR RABIES.

BY G. ARCHIE STOCKWELL, M.D., F.Z.S.,  
PORT HURON, MICH.

**I**NSUSCEPTIBILITY to toxic and septic influences as a sequel to inoculation is by no means new either in theory or practice. Since was first derived from the Levant the knowledge that an inoculated *variola* limited the fatality and ravages of *smallpox*, the principle has been applied to a wide range of maladies with varying results. It has long been understood by pathologists that there are degrees of correlation among all septic poisons, but the attempt to define a common

law therefor has not been attended with gratifying success.

More than a quarter of a century gone, De Humboldt, after a vast series of inoculations, imagined he had demonstrated a mutual prophylaxis existing between the venom of reptiles and the sepsis of that dread scourge of the tropics,—*el vomito* ;\* so, too, may be cited the more recent claims of Ferran, of Valencia, regarding cholera, or the assumed discoveries of De Freire, of Pernambuco, in yellow fever ; all of which were better based, theoretically, and productive of far more brilliant results, than has ever accrued to the rabic researches of M. Louis Pasteur, and all of which also, under segregation and careful control investigation, have been disproved. The error appears to have been the common one of mistaking *coincidences* for *facts* ; and no student in the physiological laboratory need be told that the law of coincidences is much more general in operation than has ever been surmised, and beyond all power of the human mind to grasp. Unfortunately for Pasteur also, his obstinate rejection of all forms of control experiment render his rabic labors wholly nugatory in the eyes of candid

\* Proceedings of the Royal Academy of Medicine of Havana, Cuba, 1852.

and thinking scientists, and hence not a single pathologist or physiologist of note or established reputation is found giving adherence thereto! Apparently he is wholly ignorant of that most trite of scientific aphorisms: "*By the Negative alone is the real value of the Positive demonstrated!*" Again, his secret and empirical methods; his hasty assumptions and illogical conclusions; his arrogance and impatience of restraint or correction; and above all his neglect and disparagement of the labors of others while yet appropriating their results as original with himself,—all have tended to earn for him the enmity of the ablest scientists of Europe, and caused his utterances to be regarded with suspicion. Even the ablest of his own countrymen do not hesitate (and I believe unjustly) to accuse him of fostering evil to the most base of personal ends!

Diseases to which inoculatory prophylaxis is applicable are those only which have their inception in some foreign and extraneous organism that, by one accession, secures more or less immunity from subsequent invasions; and this organism, whether *bacterium*, *micrococcus*, or "degraded form of bioplasm," demands some knowledge of its characteristics, including physiology and natural history, ere practical and intelligent application can be made thereof. Whether the malady popularly known as *hydrophobia*,\* but correctly speaking, *rabies*, possesses such organism, is a widely-mooted question: it has been the problem of centuries to the solution of which the ablest physiologists and scientists the world over have brought time, patience, energy, perseverance, and skill to bear in vain,—the "microbe theory" yet awaits the discovery of the microbes. The prevalent belief, however, is that the rabic virus does harbor a germ or organism that expends its force and energies in some mysterious and occult manner upon the central system to its derangement and exhaustion. Democritus, four hundred years prior to the Christian era, declared the "great nervous system" to be the seat of the malady, and from his time down to the present definite pathological changes in the brain and spinal cord have been sought in vain. Though discoveries have been heralded and claimed from time to time, none have withstood the test of calm, dispassionate, scientific inquiry; all have been conclusively

proven spurious, imaginary, or no way specific of the disease. *There are no post-mortem evidences in either animal or human whereby a rabies may be positively defined!*

Pasteur's earlier announcements regarding rabies, though pertinaciously put forward and asseverated, differ very materially from later theories. They include the "Discovery of a specific microbe," "New evidences regarding the communicability of rabies by the blood," and "A new theory involving the central nervous system."† He angrily and acrimoniously repudiated convincing evidence brought by his colleagues to show that the microbe described was neither new nor specific. He revamped as original and new the ideas that have made the name of Hertwig famous among pathologists, at the same time appropriating those more recent of Raynaud and Lannelongue (members of the same Academy), and finally advanced as original a theory regarding the nerve-centres and rabies so ancient that Benjamin Rush speaks of it as "old" in his day.‡

Next§ we find him appropriating the exploded theory of Davaine that the general nervous system is the channel bearing the virus to its goal,—the great nerve-centres; for which the author thereof enters the lists against him, questioning alike his integrity and ability. At this time also Pasteur professedly obtained rabic virus "*in perfect purity in the brain*," with which he secured the rabic condition "*promptly and surely*" in the creatures inoculated therewith; yet a little later it is the "*spinal cord alone*," he asserts, that is the source of the poison.

Aside from the pathological objections to the foregoing and the contradictions, Pasteur himself furnishes the best evidence of its ridiculous character in that he declares many of the creatures so experimented upon "*recovered spontaneously*," while others "*recovered and relapsed*," which, it is hardly necessary to remark, is utterly impossible of true rabies, and disproved by such evidence as Hertwig, Eichborn, Marx, Schaller, Virchow, Bollinger, Bruckmuller, Bouley, Fleming, Galtier, and other much more able and candid investigators than he. Pasteur speaks definitely also of "*rage muet*," "*rage furieuse*," and "*rage dite*

\* The word *ὑδροφοβία* was first employed by Celsus somewhere about A.D. 176 for the delineation of a *symp-tom*: hence its employment as specific of a *disease* is of questionable utility, and has been extremely provocative of error in the past.

† *Bulletin de l'Académie des Sciences* for January 18, 25, and May 31, 1881.

‡ Democritus (see preceding paragraph) is the earliest author of which we have any record who advances this claim.

§ *Académie des Sciences*, December 12, 1882.

*spontaneë*\* (dumb, furious, and spontaneous rabies), in utter unconsciousness of the fact that the first two explain degrees of virulence without being specifically distinct, and that the latter is in no sense possible. *Rabies is positively never spontaneous*, but a result of direct infection,—that is to say, every rabid creature has been inoculated by another so infected, that in turn was bitten by a third, who, in like manner, derived the disease from a fourth, and so on!†

Soon‡ Pasteur formulates a new announcement: That rabic virus multiplies in the spinal cord, and that while one portion or section may contain it in abundance, another contiguous, perhaps intervening, may be wholly inert; a proposition so absurd on its very face as to require no comment. Then, that “while virus cannot be attenuated by culture, it may be weakened by employing different species and forms of life,—i.e., it attains a descending degree of virulence by the inoculating of one species from another,” and “virus thus attenuated, if applied to the same species, remains so attenuated, direct inoculation rendering the animal proof against subsequent infection.” This is the doctrine of “fixity of virus” of which so much has been said and written; yet in the same communication he makes the perplexing assertion, “By performing inoculations in series and making transfers from one animal to another, the virus is *not* attenuated; but, on the contrary, attains a very powerful degree of activity.” And again, a little farther on, by a series of inoculations upon rabbits he is enabled to “*increase the strength of the virus to any desired degree*,” and by inoculations of monkeys (which, strange to say, for a biologist, he employs in lieu of human beings under the mistaken supposition that like physical conformation begets like physiological conditions) he secures virus “limited in virulence, further attenuated by transfer to rabbits.” Three months later§ comes the assertion that he could now render dogs “*refractaire*” to rabies “in as large numbers as any one could wish,” and yet, to this hour, it has been impossible to find one canine so rendered refractory or insusceptible, or any record of such, outside of the laboratory of the École Normale; and he now admits that *twenty-five per cent.* of his experiments have been failures. In all candor I ask, What

value can attach to such statements as these, published in *La Nature*, and uttered before the Académie des Sciences? Is this the testimony of an expert scientist, or is it of any more value because Pasteur utters it?

Next we have the claim of the molecular origin of virus, whereby Pasteur asserts his ability to determine a rabic from a non-rabic brain “with certainty,” merely by the presence of “certain infinitesimal granules;” and when it was pointed out that his infinitesimal molecular granules were the *microzymes* of M. Bechamp, and common to all brains both in health and disease, he still adheres to the statement while admitting the fact, asserting there is a difference which *he* is able to detect but cannot explain. And later, in the face of the evidence and his own admissions, he pointedly asserts the molecular granules to be veritable *contagii vivi*.

In the final announcements,|| those which embraced the much-heralded “*Method*,” Pasteur unequivocally asserts his ability to prevent rabies at any time prior to its first acute symptom, “even though years may have elapsed since the bite;” and about this time he says, through *Figaro*: “Any one bitten by a mad dog has only to present himself at the laboratory École Normale, and by inoculation I will make him wholly insusceptible to rabies even if subsequently bitten by a number of rabid dogs;” and later, in the same publication: “Whoever is bitten by a rabid dog has only to submit to my three little inoculations, and behold! he need not have the slightest fear of hydrophobia!” After all this, however, upon the death of his first patient that presumably was bitten by a rabid animal, he shortens the unlimited period to *thirty-five days*, thereby placing the patient beyond the pale by *one day*; and a little later, without any explanation, to *fifteen days*. This patient only a few days before death was pronounced virtually cured, but with the unfortunate termination he suddenly veered about, and claimed it was received only through charitable consideration, knowing full well the result that must ensue!

The method is explained as the hypodermic injection of rabic spinal cord desiccated in veal-broth, the value of the inoculation being in *inverse ratio to the quantity*, but not of its quality; and that “the strength of the cord must be such that it does not endanger the life of the subject,” . . . yet is “*more virulent than the virus of street dogs*.” This may be considered a perspicuous style of composition at

\* Yet Pasteur claims to have disproved and set at rest the theory of *spontaneous generation*!

† Ibid.

‡ February, 1884.

§ May, 1884.

the École Normale, but for my part I must confess to finding it uncommonly cloudy, and about as definite as the subsequent information that he is unable to explain how the strength of the cord used is determined, further than he "*knows by experience and looking at it.*"

The case of Joseph Meister, which is perpetually cited as evidence of the "*Method,*" demands some consideration. If the whole history is considered and weighed, the evidence is wholly of a doubtful or negative character. The boy, a child of nine years, was bitten July 4, 1885, in thirteen (some say fourteen) places, and *the wounds immediately cauterized.* The offending canine was also promptly killed, and the autopsy discovered hay, straw, and other extraneous articles in the stomach, whereupon the creature was pronounced rabid. Two assistants of M. Pasteur, to wit, Messrs. Vulpian and Grancher, decided also that the little lad was "undoubtedly doomed to rabies," because of "the number and severity of the bites!" The question is, whether this case has not done Pasteur material harm. It certainly has wrought him the enmity of eminent scientists and pathologists, who accuse him of "making capital" with dishonest motives, since every physician and veterinarian knows, or should know, that the stomachs of the *canidae* are almost never without foreign bodies,\* frequently exhibiting a general and miscellaneous assortment, induced as supposed by the presence of intestinal parasites (from which no dog is ever wholly free), or irritating materials (bones, earth, etc.) incidentally swallowed with food. The contents of the canine stomach are in no way pathognomonic of any malady; and foreign substances therein especially obtain during digestive and intestinal disturbances, or other derangements of the *primæ viæ*.

It will be observed, also, that the prompt cauterization of young Meister's wounds is altogether ignored; yet Youatt assures us that by caustics alone he preserved more than four hundred people from the horrors of rabies, and *himself* on *seven* several occasions. Again, from Pasteur's stand-point

there is apparently no limit to the period of rabic incubation, and therefore abundant opportunity remains for the disease to yet manifest itself.†

In reviewing the mechanical evidences of Pasteur's work, I avail myself of the labors of one who has given the subject of Pasteurization no slight attention. Says Dr. Charles W. Dulles,‡ in an essay read before the Philadelphia County Medical Society:

"As usual Pasteur speaks in his last communication as being '*always successful*;'§ again, his experiments have been '*innumerable, so to speak,*' . . . drawing conclusions that could only rest upon an uninterrupted series of experiments, each complete and successful throughout. Having taken the trouble to figure out what *one* such series represents, I find it means: No interruption, and no failure in experiments demanding *from one hundred and thirty to one hundred and forty rabbits, and a period of from two and a half to three years!* An interruption anywhere would condemn the whole series. Supposing, then, no interruption occurred, *how many such series could Pasteur have carried on since the time he says he began them?*

† Under the head of Paris correspondence, and date of January 15, 1886, is found in the *British Medical Journal* an account of a case by Dujardin-Beaumetz. The patient had been bitten in the hand more than a year before (in 1884) by a dog that, though it gave no evidence of rabies, was immediately killed. Some slight pain occurring in the vicinity of the wound, and excited by the expressed fear of friends, the man applied to Pasteur, who as usual made a theatrical declamation: "*I can preserve, but I do not cure!*" said the *savant* of the École Normale; and the poor fellow subsequently expired in horrible agony! If a rabies can be contracted two years after the wound is inflicted, what value have the assumed cures of Pasteur as evidence!

The theory whereby rabic virus is supposed to remain latent in the vicinity of the wound for considerable periods, varying from a few days to as many months or years, is a superstition of more than *twenty centuries'* standing, and it is surprising that enlightened and intelligent individuals, especially members of the medical profession, should yet be found giving credence and adherence thereto. Such presupposes a stasis of capillary circulation without any of the consequences that accrue to such results, and therefore involves physiological and pathological impossibilities. The truth is, there is no possible or known septic or toxic poison, whose effect is the result of direct contact with the circulatory system, that requires even half a dozen weeks for development; in that time, if it has not manifested itself, it has been eliminated, and subsequent effect is due to other and coincidental causes.

‡ *N. Y. Medical Record*, February 13, 1886.

§ Pasteur ever ignores the law or possibility of coincidence, as well as all form of control experiment (negative evidence): this is conspicuous everywhere throughout all his utterances regarding rabies.

\* Dr. Spitzka, of New York, justly celebrated as a pathologist and neurologist, declares that of more than forty canine vivisections in the laboratory of Prof. Henry Draper, in not a single subject was the stomach found without foreign bodies, such as *spools, strings, coals, ashes, hay, straw, tops, leather, rags, buttons*, etc. That this is the invariable rule, I can further corroborate from personal experience in numerous canine autopsies and dissections.

"Again, what seems a most fatal objection to the trustworthiness of these experiments is Pasteur's own admission that a full half of the spinal cords used in the crucial test upon Joseph Meister proved to have no virus at all when tested on rabbits! If this could happen in the *only* detailed experiment that he has ever recorded, what are we to believe of the experiments carried on in the secrecy of his own laboratory, of which no record has ever been given, and of which not a single witness has ever spoken?

"Another matter to be remarked is, that until recently Pasteur has given no hint that the virus of rabies could be attenuated so simply as by desiccation of the spinal cord; and yet, if his own statements are to be accepted, he must have been far advanced in his experience with this method at the time he was startling the world with his backward and forward modifications of the virus by means of monkeys and rabbits, and presenting that as the *only* way of procuring material for inoculations.

"If we take the trouble to place side by side Pasteur's statements at different times, it is found that they are so inconsistent that the cordial acceptance of any one of them demands that those preceding be wholly banished from memory. At first it was in the brain that the virus was to be obtained; then trephining and intradural inoculation was the sovereign method; then intravenous inoculation simplified the matter; then blood was a good virus (though this had been previously denied by him in his second communication to the *Académie*); then smaller quantities procured the fiercer rabies; then inoculations in series modified the virus after many variations; then a few monkeys and rabbits did the work; and, to crown all, ignoring the evidences of his own work in regard to *charbon* and *chicken-cholera*, he declares that the protective character of the virus depends upon a reduction of quantity, but *not in the virulence of the material* used! And when we catch our breath, we cannot but recall what has gone before and ask, *If the hypodermic use of graduated virus was the means Pasteur found most readily produced the most furious form of rabies in February, 1884, when he must have been half-way through the series of experiments upon which his final communication is made, how could the remaining half have sufficed to prove the same procedure would exert a kind and protecting influence on the same animal and in man!*

"Also, Pasteur actually intimates that the

virus of rabies may be formed of two distinct substances,\* and that by the side of the one which is animate and capable of germinating in the nervous system there may be another inanimate, having the power, when in proper proportions, to arrest the development in the former!"

The latest announcement of the French *savant* is that his inoculations "have proved *successful*" in some sixteen hundred and fifty cases,—cases which include Joseph Meister, the four Newark children,—Kaufmann, Salter, Bucklin, Miss Morosini,—Metzler, and all who *were not* bitten by rabid dogs,† to say nothing of some scores of healthy people who underwent the operation from curiosity or to secure the immunity it is supposed to insure. From the remaining number must be deducted *ninety-five per cent.*‡ for those bitten by rabid creatures who would in any event escape all manifestations of the disease. From the balance further subtract those in whom the disease has not yet had time to develop (accepting Pasteur's estimate thereof).

With such essential depletions, even ignoring the last, the figures assume such insignificant proportions as to be practically without value. To be sure, Pasteur has recently claimed, or others have claimed for him, that

\* This is subsequently affirmed most positively by Dr. A. Cartaz in *La Nature* on the strength of Pasteur's own assertions; also by M. Vignal, another mouth-piece of the *École Normale*.

† Few of the cases whose positive history can be traced afford so favorable evidence as even that of Joseph Meister. The dogs that wounded the Newark children are still alive and well, having been quarantined for observation, and two of the children who did not visit Pasteur fared equally as well as those that did. Kauffmann and Bucklin were not even bitten, but had some portion of their bodies caressed by the tongue of canines that gave no evidences of *any* disease; and the evidence in Miss Morosini's case rests solely upon one little feather found within the stomach of her pet.

‡ The proportion of dogs—much less human beings—that are infected by the bite of rabid creatures is extremely small. Nine different attempts to procure the disease in the famous poodle of Hertwig failed. Dogs experimentally bitten from three to sixteen times each, at veterinary schools in Germany and throughout Europe, suffered not the slightest inconvenience therefrom; and individual cases with greater ratios are common. Grove admits that but one dog out of every *twenty* bitten by other and *known* rabid dogs ever contracts "canine madness." John Hunter says, one of *twenty-one*; Hamilton, one in *twenty-five*; Nieumann, one of *thirty-five*; and Fabre's extended researches revealed but a total of thirty-one out of eight hundred and ninety-two cases,—*less than four per cent.* Statistics embodying larger figures on close scrutiny are found to make no distinction between specific or true rabies and a simple neurosis inducing a spurious rabies.

no inoculation is ever undertaken until a certificate is presented that the person has been bitten by a rabid dog ; but this, of personal knowledge, I know to be untrue.\* Again, since there are positively no evidences either in the life or death of a canine whereby a rabies may be with certainty determined, even by the most profound veterinarian and physiologist, of what value is such certificate ?

*Twenty-one* deaths have followed Pasteur's ministrations, in spite of the boasted success of the "*method*," all of which, with the exception of the Pellitier child, came within the *fifteen-day limit*, and for a majority of which the lame explanations were offered that different species of *canide* induced different degrees of virulence, or that they were "*bitten near the brain*." This latter supposition, that the point of inoculation has direct reference to the period of incubation, is another theory borrowed from Davaine, and long since repudiated by the latter ; moreover, it has been repeatedly disproved, even so recently as April, 1884, by Dujardin-Beaumetz in a communication to the very Academy of which Pasteur is a member, embodying a synopsis of thirty-four cases occurring within the Department of the Seine !

Within the last hundred days no less than *six cases* are reported as having succumbed to rabies, all of which had been under Pasteur's hands and pronounced by him "*cured*." On the 27th of April a young girl from the Jura was bitten, and reached the laboratory of the École Normale nine days later. At the end of fifteen days she was discharged with the assurance all danger had been averted ; yet on the forty-third day following the first inoculation she died of rabies. Also, the *Journal de Médecine de Paris* in July reported that a Russian woman had just died of rabies at her own home in St. Petersburg, whither she had returned after undergoing Pasteur's inoculations, and assured by him she was "*completely cured*." On the 21st of July a man bitten by a rabid cat died at Grenoble who had undergone the preventive treatment of the "*Method*" from May 4 to May 13. Of seven persons bitten by a mad dog (not wolf this time) sent from Russia, and all treated by Pasteur, three succumbed to this fatal malady shortly after their return home. And yet Pasteur continues to announce the certainty (*surement*) of

his "*Method*," and, what is more, secures converts !

True rabies presents multiple and varied phenomena, without a single constant feature, and hence its presence is with difficulty determined even by the most expert. Indeed, so erratic are its progressions and manifestations, that it is a greatly-mooted question whether it exists as a malady *sui generis*.† More than sixty diseases in man, and double the number in the dog, are constantly being mistaken for rabies by the most expert members of the medical (general and veterinary) professions. The former include disorders of the stomach, especially in very young children, as well as inflammation of the stomach and œsophagus in adults ; disorders of the respiratory apparatus ;‡ disorders of the circulatory apparatus ;§ systemic conditions, including rheumatic fever, gout,|| *uræmia*, pernicious an-

† Wounds, even though made by one of the carnivora (*canide*), are in no sense presumptive of rabies ; even the vast majority of rabic cases are, undoubtedly, the sequel of functional disturbances of nerve-centres as the result (a) of simple *septicæmias*, and (b) the fears and imaginations of the individuals, their friends and advisers. When we consider the influences of fear, anxiety, joy, and anger upon the great nerve-centres, remembering that these are capable of so modifying any and all the secretions of the economy, even to the milk within the maternal breast, or the saliva, until toxic properties are developed ; that persons have died within a few moments, or hours, from these and kindred causes ; that individuals in robust health thereby are permanently invalidated, rendered insane, thrown into convulsions and catalepsies, and driven to *felo-de-se* : we understand how cases of so-called *hydrophobia* may, and do, arise, especially if by any stretch of the imagination the animal can be linked therewith. No physician or neurologist, however able, expert, or talented, has ever been permitted to fathom the mysterious workings of the nervous centres under profound agitation of the mind, or to discover what influence the perturbed mind may have reflexly upon the nervous system, or through it upon morbid agencies that may already have been implanted within the economy. And this is even more true of the canine than the human subject. Wounds made by *carnivora* (flesh-eaters) are always prone to develop *septicæmia* in any form of life, by reason of putrid and decaying particles that may be retained in and about the teeth and mouth.

‡ See Transactions of the Medical Society of the State of Pennsylvania for 1884. The resemblance in many of their symptoms of diseases of the respiratory tract to rabies is so marked that Aromatarius, in 1625, devoted a monograph to proving rabies was but a *contagious sore throat*.

§ That inflammatory conditions of the heart and its envelopes (*pericarditis*, *endocarditis*, etc.) do frequently give rise to conditions that are mistaken for genuine manifestations of rabies, is a fact well recognized in most treatises and monographs upon the subject.

|| H. Sutton.

\* M. Wm. Vignal writes (in *N. Y. Medical Abstract* for May, 1886) : " Although Pasteur asks for a certificate, yet when one is not forthcoming and there is reason to believe the dog is mad, he inoculates ! "

*æmia*, intermittent fever, typhus, mercurialization,\* pregnancy,† bronchocele, poisoning by iodo-hydrargyrate of potassium,\* deuto-iodide of mercury,\* digitalis, and various toxic plants; disorders of the nervous system,—meningitis, pachymeningitis, tumors, abscesses, and parasites of the brain, simple neuritis, acute mania, spinal sclerosis, acute delirium,‡ alcoholism, tetanus, epilepsy, hysteria, and the use and abuse of chloral, chloroform, ethyl bromide, hyoscyamus, cocaine, betel, etc. In the animal, also, we find the following: "tooth-ache," "earache," canker (mastoid disease), abscesses, *enteritis*, *gastritis*, *gastro-enteritis*, *ileus*, *peritonitis*, *nephritis*, *cellulitis*, *cystitis*, intestinal obstruction and perforation, rheumatisms, heart, throat, and lung difficulties, epizootics and distempers, parasites in throat, nasal cavity (*pentastomæ* and *æstriei*), kidneys, heart, intestines, liver, brain, muscles, etc.; skin-diseases (*mange*); diseases of the eye; "sea-sickness"; "land-sickness" (following long voyages); ague, fevers, *chorea*, epilepsy, epileptiform spasms, spasms of reflex origin; pure psychoses (*mania* and *melancholia*); *anæmia*, *uræmia*, *pyæmia*, *septicæmia*; metallic and corrosive poisons (copper, arsenic, benzoic acids, mercury, etc.); *hydrocephalus*, *meningitis*, *encephalitis*; and in fact the whole class of nervous and mental diseases to which canines are subject in *even greater degree than man*, and whose existence has not even been suspected by a majority of observers. Personally, after more than twenty years' experience as physician, dog-owner, dog-breeder, and student of canine and comparative medicine and physiology, I have yet to meet with an *absolute* case of rabies in the dog; and of some scores of so-called hydrophobic animals, alive and dead, presented for my inspection, one and all were found to have suffered from other and innocuous maladies.§

\* Dr. Reid, in 1817, mentions a young woman who died as a sequel to profound mercurialization induced with a view to relieving a tertiary syphilis. I am personally familiar with a like case induced by the combination of mercury biniiodide and iodide of potassium. The immediate cause of death in both cases was really ulcerative stomatitis.

† Doleris and Mazars de Cazelles mention "*hydrophobia*" as occurring as a sequel to pregnancy; the latter says *eleven times* in the same individual.

‡ Westphal, in *Archives für Psychiatrie*, II., says that acute delirium is often confounded with rabies, and that in "*depressed and hypochondriacal subjects the bite of a healthy dog will cause hydrophobia.*"

§ Three skulls recently came into my possession, by favor of a skilled member of the veterinary profession, of dogs slain as infected with "hydrophobia," and yet

Unfortunately, the testimony of Pasteur as to what constitutes rabies, owing to his total lack of medical education and training,|| is valueless. It is something more than strange that the dictum of such a visionary should be received so implicitly, while the evidence of a Huxley, Owen, Hæckel, or other eminent biologist possessed of sound physiological education upon this particular subject, would pass almost unheeded save as corroborated from other sources; and that, too, in the face of the fact that he (Pasteur) exhibits a total lack of familiarity with the history of the disease, past and present, and formulates as specific manifestations trains of symptoms that are common to scores of simple maladies, and in no sense pathognomonic of any one.¶ Every physiologist or pathologist knows that intradural inoculation,—the means employed by Pasteur to secure "infected" (?) spinal cords,

all suffered no other malady than the so-called "canker," *otitis cellulosa*, or mastoid disease.

|| In the face of the evidence so frequently offered, there are those who persist in believing M. Pasteur an epitome of biological, medical, physiological, pathological, and chemical attainments. To such I will not offer evidence personally derived, but recommend the perusal of the volume entitled "Pasteur: his Life and Labors," as edited by his *son-in-law* and revised by *himself*! For the benefit of such as may not encounter this most extraordinary work, I quote a few paragraphs from an article by Dr. Frank S. Billings, an intimate and ardent supporter and admirer of the man, as found in the April (1886) number of the *Journal of Comparative Medicine and Surgery*: "Pasteur is no chemist, . . . he is not even a physiological chemist, nor has he any professional knowledge of the fundamental branches of medicine: and last, but most of all, we fail entirely in perceiving any evidence of broad education in biology, zoology, and philosophy, which is absolutely necessary to a man having comprehensive views in science. . . . Pasteur did not approach any of them (anthrax, chicken-cholera, the swine-plague, and rabies) as a pathologist; . . . he had no interest in these diseases, *as such*. He did not care an iota about their nature other than their contagiousness; and so far as the nature of the pathological changes occurring in them, they had no interest for him at all. To Pasteur they were simply a given something; in the tissues of these animals there is lodged a specific quantity, this quantity the contagious or infecting principle. The next thing was, what can be done with this principle? Pasteur is no bacteriologist; not one of his statements as to the existence of a specific form in a given disease are to be trusted unless we can find collateral support for them in the works of others. . . . In fact, unlike such men as Darwin or Virchow, Pasteur is not a man of ideas, not a deep thinker; he will never move the world as a great teacher, but simply as a contributor of new evidence; . . . he ignores the work of others, and to my mind the reason for this is that it is largely medical, and hence, knowing nothing of it, it would be of little use to him."

¶ See page 680.

—even of the simplest septic or aseptic product, is almost invariably attended with consequences most grave to the creature so operated upon. Naturally, paralysis most frequently follows, yet it is the evidences of paralysis upon which Pasteur so confidently relies for his diagnosis of rabies. If an opening be made in the cranium of the dog, or the rabbit,\* directly over the nerve-centres,—and the nervous system of either is much more impressible than that of man,—and a drop of pus, blood, or *bouillon* introduced in the submeningeal space, the miracle would be if the creature *did not* speedily develop a paralysis of facial muscles and posterior extremities!† M. Paul Bouillier, a distinguished veterinarian and a member of the Parisian Council, declares—and there is no individual in better position to *know*—that Pasteur's inoculations have not the slightest preventive or mitigating influence upon rabies, either in the canine or human subject; that the animals that provide the so-called virus are not rabid, but sufferers from simple cerebral and meningeal affections artificially induced; that the persons supposed to have been cured by the "*Methode*" were never affected by true rabic virus,—either the creatures that produced the wounds were innoxious, or the virus individually was inoperative; and finally, after having given the matter his personal attention, arriving at the foregoing conclusions, he challenged M. Pasteur to personal test,—each to be bitten by a *known* rabic animal. M. Bouillier to be cauterized, and M. Pasteur to rely upon his inoculations.

Complete paralysis as the sequel of submeningeal inoculation constitutes the "dumb rabies" (*rage muet*) of M. Pasteur, while a less diffuse form of intradural inflammation, provoking delirium, either with or without subsequent palsy, becomes a "*rage furieuse*" (furious rabies). This accounts also in some measure for the assertion that the latter is induced by employing minute quantities of

virus, the larger proportion procuring *rage muet*, which he mistakenly supposes to be the least specific and virulent form of disease: an error that would scarce be perpetrated by a pathologist. I now recall four comparatively recent cases whereby death was induced in the human adult from intracranial (cerebral) abscess, and in not one of which a drachm of pus was found on autopsical examination. One yielded only about one-third the quantity; and yet paralysis was present, along with other symptoms that, measured by the Pasteurian standard, would have made a diagnosis other than rabies a criminal error!

Fairly familiar with the man, and his methods and abilities, I have no desire to question Pasteur's primary integrity or original purity of purpose. On the contrary, I would accord him every honor that is his due. I regret that his efforts regarding rabies have not some definite basis, and that they are not more deserving of support. Unfortunately, he has been led into error,—the error of ignorance of his subject,—while the constant empirical promulgation of his peculiar ideas retards the wheels of progress, whereby science is made to suffer. I must admit it is difficult to criticise the man fairly or justly, since his work for the most part consists of mere assertion. Again, no one can follow his work. Apparently he cannot follow it himself. Take any one of his utterances, and one is amazed to find a contradictory mass of statements, such as have never emanated from any other source. We discover no well-arranged, systematic records of study and experiment, along with data, facts, and conclusions carefully considered and worked out,—the usual evidences of the efforts of the true scientist; but we find positive assertions to-day as positively controverted to-morrow, both overwhelmed and denied on the third occasion. Judged by any standard, it is impossible to accord him rank as a scientist, and yet carefully considering his real and brilliant discoveries, he deserves high place in general estimation. Both visionary and erratic, without any consideration of cause and effect save as desired, demanded, and expected, he hails with delight all evidences that may present themselves as positives, while wholly ignoring the negatives: for the time being he is the man of a single idea, and all things, therefore, must accommodate themselves and become subservient to that idea. Those who persistently follow one train of thought with the one end in view to the exclusion of everything else, are sure

\* It is a well-known fact that the *leporida* (rabbits and hares), though suffering from rabies, exhibit no evidences of specificity. How, then, does Pasteur definitely decide whether he succeeds in producing the disease in this order of animals is an interesting subject of query.

† See account of six experiments made by Dr. E. C. Spitzka, wherein the brains of as many dogs were inoculated with normal spinal cord of a calf, with emulsion of pons and cerebellum from a patient who had succumbed to specific rabies, with yellow soap, and stale or putrid urine of horses, as communicated to (and animals exhibited before) the Society of Medical Jurisprudence and State Medicine.—*Journal of Comparative Medicine and Surgery*, July, 1886.

to discover evidences that to their own mental vision are incontrovertible. An hour's conversation with Pasteur is convincing evidence that he must be included in this category. Add, too, a hasty temper, overweening confidence and egotism, impatience of slow experiment and inability to await definite results, dread of being forestalled and supplanted in public favor, and then, and then only, can a true estimate of the man be had. Even Napoleon had not a more exalted idea of "*destiny*." Such characteristics cannot but tend to the formulation of crude and ill-drawn conclusions as facts, trusting to the varied chapters of accidents to sustain them in the future as they have done in the past. Nevertheless, even such genius as may be granted Pasteur does not foster confidence in his assertions or abilities. What we know of ferments, of anthrax,\* chicken-cholera, vine and silk-worm disease, is in great measure due, directly or indirectly, to his labors; but since his unqualified and positive promulgation of the rabic theory, and the flat failure of the swine-cholera† prophylaxis, his assertions will scarce meet the cordial approbation of candid scientists until corroborated from other and more able sources. Indeed, his assertions have never been received at home with the cordiality and reverence with which they are popularly accredited in the United States,—error derived from idle, irresponsible communications to the medical and general press; and, save as the name of M. Roux, or M. Wasserschlag, is associated therewith, little heed is given thereto. One of his greatest inconsistencies, the one which has done more to promote suspicion and distrust in thinking and observant minds, is his oft-repeated assertion that the "*Method*" is "*sure, simple, safe, and practicable*." Yet at the same time he positively avers that, outside of his laboratory, "there is not a single individual capable of undertaking the treatment with *surement*." Another is, "Inoculating a quantity of virus insufficient to produce the symptoms of canine madness (*phénomènes rabiques*) does not confer immunity,—that is, the remedy must needs be more virulent, and consequently more dangerous than the virus that

obtains the disease,—"*more virulent than (the bite of) street dogs!*"

It must be remembered that Pasteur has wholly abandoned the saliva as a natural virus,—the only factor known to positively communicate the malady,—substituting instead emulsions or macerations of spinal cord.‡ That the latter are capable of inducing simple septic inflammation does not admit of a doubt; and it is this sepsis that, without either evidence or experience, he so unhesitatingly and arbitrarily pronounces "*rabies*." If his experiments prove anything, it is only that these inoculations, under certain conditions, may render different forms of animal life "*refractaire*" to the condition the virus itself induces; and here is embodied one of the very principles at which we have been accustomed to sneer when advanced by our brethren of the strict and ultra-homœopathic persuasion.

In lieu of other evidence, to witness the inoculations as publicly performed at the laboratory École Normale alone would be sufficient to excite grave doubts of their utility, providing one can resist the personal magnetism of Pasteur sufficiently long for correct observation. Daily some half hundred or more people crowd the operating-room, and without any rule of procedure or preference walk about a table upon which is placed the array of glasses that we are told contain virus in *bouillon* in varying degrees of culture and virulence. No reference to case-book or register is ever made, even if such be kept; but M. Grancher inoculates (for Pasteur, who is disqualified by lack of medical education under French law) in a grossly unscientific, not to say slipshod, manner. It is impossible he should know who is who, since he rarely lifts his eyes to identify the subject, and he receives the syringe already *filled*, often before

\* Already comes the news from France that the preventive method for charbon is unsatisfactory. How far this is truth or due merely to rumor I have no means of knowing at present.

† See Department of Agriculture Reports of the past four years; also Report of the State Veterinarian of Nebraska, and his utterances in the *American Veterinary Review* for the current year.

‡ Galtier, of Lyons, a much more able, thorough, and candid experimenter than Pasteur, would seem to have set this matter at rest by collecting and verifying the experiences of others in connection with his own work. By a number of series of experiments, secured further by careful control evidence, he has demonstrated the fact that the *materies morbi* of rabies is confined to the saliva of the true carnivora alone, that inoculation with blood, portions of salivary and parotid glands, portions of the contents of stomach, of brain and spinal cord, or their fluids, all lead to no infection. He further cultivated virus obtained from the *canide* in normal saliva, and vaccinated guinea-pigs and rabbits that died in from four to twelve days; but in retro-vaccination of dogs by means of the salivary products of these creatures, he was unable to secure a rabies in a single instance. N.B.—*No non-carnivorous creature can communicate a rabies!*

it is known who the patient will be, from the hand of a servitor, and empties it into the right or left abdominal space, as the case may be, without question or inquiry!

The results of the "*Method*" are easily summed up: Twenty-one deaths, with no pertinent or satisfactory explanation; some hundreds of people to bear witness that it is productive of no immediate harm; as many more to illustrate the well-understood advantage of fears allayed; in all no more than has accrued to *aristolochia indica*, *simaba cedron*, *inula*, *xanthium spinosum*, *planta genista*, applications of human fæces, Sanjoie pill, "the false tongue of the colt," "mad-stones," and other nostrums innumerable. *Per contra*: It has induced and fostered a widely-spread irrational epidemic of *lyssaphobia*, or *rabiphobia* if you prefer; catered to an irresponsible and sensational press; promoted the sale of nostrums and encouraged vile quackery; is responsible for numberless suicides, deaths from spurious rabies, and at least one *murder most foul*;\* and brought about a heartless and cruel persecution of innumerable and inoffensive canines!

The science of the present era is nothing if not progressive, but it demands *truths*, not mere vague theories and unsupported inferences. Superstition is the refuge only of the timid and inconsequent; and to the superstitions of twenty-two centuries and more Pasteurism owes its rise; superstitions from which the medical profession, alas! is none too free, and that inculcates insane fears that lead to grasping at straws. There are no parallels between its teachings and those of Jenner, to which it has so often been compared, since the latter was derived from fixed pathological data, entirely lacking to the former, which rests solely upon the unsupported and self-contradictory assertions of its author. Neither is the opposition to Pasteur the outcome of bigotry, intolerance, conservatism, or jealousy, as many are led and willing to believe, but merely a demand for hard, stern facts, stripped from all jugglery and superstition,—a demand of science that an intangible theory be made tangible, and reconciled to existing and firmly established physiological and pathological laws which it controverts. *Verborum sat!*

\* (Associated Press despatches.) "Cohoes, N. Y., February 3, 1886.—Sunday night George Waterhouse . . . showed signs of hydrophobia. He grew rapidly worse. . . . The physicians saw there was no hope of saving him, and to end his sufferings ordered that he be smothered, which was done. Waterhouse was bitten by a dog six years ago, while a resident of Lansingburg!"

## SEPULTURE VERSUS CREMATION.

BY GEORGE HAY, M.D., PITTSBURG, PA.

EPISTLE to the Hebrews, chapter ix. verse 27: "It is appointed unto men once to die, but after this"—decomposition. This statement is true not only as regards men, but as respects all other beasts. The word "beasts" is used here advisedly, for, from the naturalist's point of view, man is a beast and nothing else. Admitted at once that he is the highest of the beasts in organization, and by consequence in physical and mental capacity, still that does not alter the essential fact that he is a beast. In common, then, with all other beasts, certain elements enter into his composition. For the soft tissues those elements are carbon, hydrogen, oxygen, nitrogen, sulphur, and phosphorus; for the hard tissues the elements are in a limited sense calcium, phosphorus, carbon and oxygen, forming phosphate and carbonate of lime in the bones and teeth. Those just enumerated constitute by far the greater bulk of the animal, although very small proportions exist of many other elements. For a longer or shorter time the individual man lives,—that is to say, the vital functions of waste and repair are carried on; but sooner or later, as the results of such accidents as violence or disease, or as a consequence of that impairment of vital functions popularly termed old age, he dies. At the moment of death all vital functions have ceased, and another kind of energy at once takes possession of the dead body,—the energy, viz., of decomposition. Bearing in mind the elements mentioned above, what are the results when a body is left freely to decompose in the open air? They are carbonic acid, water, ammonia, phosphoretted hydrogen and sulphuretted hydrogen. The carbonic acid and ammonia are the aerial food of plants. The rapidity of such decomposition would be determined by the temperature and moisture of the surrounding air. Bacteria and vibriones would find their way to the corpse, and the result would be putrefaction, evolving the gases already mentioned, accompanied by what is popularly termed a stench, and producing carrion. Leaving out of the account carrion-eating beasts, birds, and insects, and also carrion-eating larvæ of insects which are not themselves carrion-eaters, the gases already mentioned would be the results of the decomposition of the soft tissues and also of the organic portion of the hard tissues. After a time all that would be

left would be the inorganic portion of the hard tissues, consisting mainly, as already stated, of phosphate and carbonate of lime, in a pulverulent condition. This powder would be blown about by the winds, and scattered over the soil, where it would ultimately be dissolved by water containing carbonic and sulphuric acids, and thus be rendered capable of absorption by the roots of plants as part of their inorganic food. The phosphoretted hydrogen and sulphuretted hydrogen from the decomposition of the organic tissues would ultimately be converted into phosphoric acid, sulphuric acid, and water by oxidation. Thus the whole body would ultimately find its way back to the earth whence it was derived, to reappear in the shape of grasses (including cereals) and other plants, food for man and other beasts. Why, then, when nature so effectually disposes of the dead body, do human beings bury their dead? For two principal reasons, although perhaps few persons would ever stop to make the inquiry. In the first place, the stench is exceedingly unpleasant; and, secondly, the carrion-eating insects are particularly dangerous to the living. This last fact the writer has great occasion to remember, for only last summer he was bitten by one of those insects, and ran a great risk of losing his life in consequence. So, people bury their dead. How? A pit from six to eight feet deep is dug in the earth, and the body, either enclosed in a coffin or wrapped in a sheet, is laid at the bottom of the pit, and covered with the earth which had been taken from the hole. Frequently a stone slab is erected by "affectionate" friends, upon which are recorded the superhuman virtues of him or her who lies beneath. This hole is called a grave, a word derived from the Anglo-Saxon *græf*, having the same signification. The body is said to be buried or *interred* (from the Latin *in terra*),—i.e., put in the earth. At the depth of six or eight feet precisely the same ultimate changes take place as when the body is left spontaneously to decompose with free exposure, as above described. It is doubtful, however, whether real putrefaction takes place at this depth; and the writer is somewhat inclined to think that the change is somewhat analogous to *eremacausis* or decay, for it is very questionable whether bacteria and vibriones can be alive and active at the depth of eight feet. One thing, however, is certain, and that is, that in the grave the process of decomposition proceeds much more slowly than it does

at the earth's surface. Still, the ultimate results are the same. The carbonic acid, water, and ammonia, instead of being entirely dissipated in the atmosphere, would mostly be carried by water into springs and streams, as also the phosphates and carbonates from the bones and teeth. These substances would form the food of lacustrine, fluviatile, and marine plants, which would in their turn afford food to mollusca and fishes, and thus again become the food of man and other beasts. Thus nature has again effectually disposed of the dead body, but by burial the stench and the insects have been entirely avoided. Suppose now that the person has died from scarlet fever, or smallpox, or some other infectious disease, and that he has been buried within the limits of a city. Cities have drains and sewers, the surface openings to which are frequently very ineffectually trapped; fluids draining from the dead bodies may easily find their way into the sewers, a sudden gust of gas occasioned by some disturbance in the sewer contents may carry the infection of those diseases into the city atmosphere, and thus reproduce the diseases in the living. On the other hand, diseases may be swallowed,—e.g., typhoid fever and cholera Asiatica. The fluids draining from bodies may easily carry those diseases into surface wells, whose water being imbibed may produce the disease in the living, or the decomposing fluids getting into the surface wells may form a *nidus* for other diseases. Such and other considerations lead to the conclusion that intra-mural cemeteries are exceedingly dangerous. All cemeteries ought to be situated a mile or two outside of city limits, away from drains, wells, or other direct means of contagion or infection. If such precautions were adopted and rigorously enforced, having due regard to the conditions and surroundings of the cemeteries, sepulture would be rendered perfectly safe from a sanitary point of view. Reference has already been made to the retardation of decomposition by burial. If before burial the body has been subjected to the modern process of "embalming," decomposition will be still more slow. The writer has already examined in his own laboratory several embalming fluids used by undertakers, and has found them all to consist chiefly of solutions of arsenite or arseniate of sodium. It is easy to see that such "embalming" might be used to mask crime, and, in point of fact, "embalming," as at present carried on, puts a premium upon murder by arsenical poisoning. This fact the writer

brought first to the notice of the medical profession in a paper "On Modern Embalming," published in the Philadelphia *Medical Times* of August 19, 1876, to which the reader is referred.

Cremation comes now to be considered. The word cremation is derived from the Latin *cremo*, I burn, and means the act of burning, with the special signification of burning dead bodies. In the year 1876 the world was thrown into a ferment by the news that the body of a German baron by the name of De Palm was to be burnt to ashes at Little Washington, a few miles from Pittsburgh. A doctor of the name of Le Moyne (his own name may have suggested the practice, the French words *le moine* signifying the warming-pan) had constructed a crematory. The crematory consisted essentially of a fire-clay gas retort nine feet long, thirty-two inches wide inside by eighteen inches high inside, and two and one-half to three inches thick. The retort had an iron door in front, with bolts to secure it, a dozen one-inch holes on each side just above the bottom, and a six-inch hole at top, which communicated with the chimney. The retort was built in with appropriate brickwork, and was heated by a furnace placed underneath it. When a bright red heat had been attained, the body, supported on a light iron grating, and covered with a shroud soaked with alum, was thrust into the retort, the door in front was closed, and in a few hours nothing remained but ash. After the retort had cooled, the ash was collected and placed in an urn, and was doubtless labelled "Ashes of Baron de Palm, cremated at Little Washington, A.D. 1876." Before placing the body in this retort the fire is allowed to burn quite low, the strong draught takes a current of air through each of the twenty-four one-inch holes in the sides, and a powerful heat being radiated from the walls of the retort upon the dead body, combustion goes on, and the products of combustion are carried by the draught through the six-inch hole into the chimney. Considerable improvements might be made in this apparatus, but these are beyond the scope of this article, although the writer has mentioned the fact to the makers of this retort, the Messrs. Gardner Brothers, of Pittsburgh.

Let us notice now the products of combustion of a dead body. In the Edinburgh *Weekly Scotsman* of Saturday, May 3, 1884, under the heading "Imperial Parliament," in the section "Dead (Regulations) Bill," Sir Lyon Playfair makes the following state-

ments: "The body yields in the furnace the very same gases which it yields from the soil. The time only differs. In the one case, an hour is sufficient; in the other case, twenty years may not suffice. The ultimate processes are not merely similar, they are absolutely identical." Such statements delivered *ex cathedra*, as it were, by a gentleman of Sir Lyon Playfair's scientific and legislative position, are apt to be received by the general public *sine grano salis* and without examination. Nevertheless, the writer presumes to doubt the identity of the processes of burial and cremation even in their ultimate products. In burial the products are carbonic acid, water, ammonia, sulphuretted hydrogen, and phosphoretted hydrogen, the two last being ultimately converted into sulphuric and phosphoric acids. In cremation, if the process of combustion is perfect, the products are carbonic acid, water, nitrogen, uncombined phosphoric acid and sulphurous acid, the last being ultimately converted into sulphuric acid. In cremation, if the process of combustion is perfect, no ammonia whatever is formed, all the nitrogen being liberated as gas. Liebig, "Agricultural Chemistry," in the chapter on "Eremacausis of Substances containing Nitrogen," says, "When azotized substances are burned at high temperatures, their nitrogen does not enter into combination with oxygen;" "and in the same way the substances containing nitrogen give out that element in its gaseous form." Here, therefore, is one very important difference between burial and cremation. In cremation the nitrogen of the organic substances is thrown as gas into the atmosphere to add to the quantity of nitrogen which it already contains. Liebig again, "On the Origin and Assimilation of Nitrogen," writes, "We have not the slightest reason for believing that the nitrogen of the atmosphere takes part in the processes of assimilation of plants and animals." "But there are, on the other hand, numerous facts showing that the formation in plants of substances containing nitrogen, such as gluten, takes place in proportion to the quantity of this element which is conveyed to their roots in the state of ammonia, derived from the putrefaction of animal matter." In short, it is only in the form of ammonia that plants can take up nitrogen at all, whether by their roots or leaves, and that some plants do take it up by their leaves is certain. Everybody, therefore, that is cremated robs either water or atmosphere of so much ammonia, and to that extent the process of cremation is a wasteful interference

with nature's operations. This is one objection to cremation ; but there are others.

The incombustible portion of the body, the ash remaining after the process of combustion is completed, is consigned to an urn. This ash consists principally of phosphate of lime, —*bone-earth* ; but it contains also the ash of the muscles, the ash of the blood, and the ash of all other tissues and organs. In the urn it is absolutely useless,—it fulfils no function in nature. It has taken the living body perhaps seventy years to collect the few pounds of bone-earth which constitute the inorganic portion of its skeleton. By the process of burial all this bone-earth would ultimately have been returned to the earth from whence it came, or made otherwise, as above indicated, available for the food of man. Cremation robs nature of all this valuable phosphate, a substance without which no cereal plants can live. Here, again, is a wasteful interference with nature's operations. Remark here also the decided *non-identity* of cremation and burial in respect to the disposal of the phosphates.

Beyond the shadow of a doubt hundreds of corpses are every year consigned to the grave, the victims of secret poisoning. These cases have escaped the cognizance of the physician, but occasionally some suspicious *post-mortem* circumstance leads to the disinterment of the victim's body ; the toxicologist discovers the poison ; the murderer is hanged. Suppose, however, that the body has been cremated. If the poison has been organic, or one of the volatile metals, such poison cannot be found in the ashes, the crime is effectually concealed, the murderer goes scot-free, and even the slight check which the possibility of an investigation would afford has been completely removed by cremation. Here is another serious objection to the practice.

Putting aside all special pleading, in which the literature of this subject too much abounds, the writer thinks that from the foregoing considerations several conclusions may be drawn.

1. Considered merely as a measure of sanitation, cremation, as a means of disposing of the dead body, is perfect when properly performed.

2. As a measure of sanitation, when properly performed and under proper conditions, sepulture, as a means to the same end, is also perfect.

3. As an economic measure, cremation is faulty in the extreme, being wasteful and destructive.

4. As an economic measure, sepulture is

much less faulty than cremation, being, to a certain extent, conservative.

5. As a testificatory measure, cremation cannot be entertained at all, for it completely destroys all physical testimony in cases of crime which the cadaver might afford.

6. As a testificatory measure, sepulture, to a certain extent, is satisfactory, for its tendency is to conserve the physical evidences of crime.

#### CHLORIDE OF SODIUM IN THE TREATMENT OF BRIGHT'S DISEASE.

DR. ALLARD MEMMINGER (*New York Med. Journal*, July 31, 1886) recommends the use of sodium chloride in the treatment of Bright's disease. He claims that this drug will produce a decrease in the amount of albumen and an increase in the amount of urea, and a very marked increase in the quantity of chlorides eliminated. He orders 10-grain doses of the chloride in gelatin-capsules three times a day, by preference one hour after or before meals, and directs the patient on the slightest intimation of nausea immediately to resume a recumbent posture, and there remain for an hour or so. The second day of treatment he increases the dose to two capsules three times a day, and every other day he increases by one capsule until the patient is taking five capsules three times daily. About this time he claims that the good effects of the treatment will be apparent, not only from the improvement in subjective and objective symptoms of the patient, but from the improvement in the condition of his urine. Albumen will of course at this period be found still in abundance if the case is at all a grave one. At this juncture Dr. Memminger directs the chloride to be diminished in quantity, and now gives the patient two capsules three times a day, stopping it temporarily if any nausea is produced. If the albumen is again found to increase and the urea and chlorides diminished, large doses are at once resumed. The effects of this treatment are found in the reduction of the albumen, an increase in the urea and chlorides eliminated, and the removal of headache, œdema, low spirits, general weakness, and anæmia. He claims that it is harmless if properly administered ; its effects are uniform, and it may be employed as an adjunct to all recognized modes of treatment without detriment to the patient.

### THE MEDICAL ASPECTS OF THE NORTH-WEST.

THE importance of Switzerland to Europe as a playground is very great, but in the creation of North America the necessity of some such central spot seems to have been overlooked. This is especially unfortunate, since the temperament of our people leads them more and more to do twelve months' work in eleven months, and during the remainder of the year recuperate from the effects of this folly. Recuperation at a fashionable watering-place is usually as satisfactory in its results as trying to save a candle by burning the lower end. Mental rest, physical exercise, the open air, these are the necessities of the summer-time. The Adirondacks in New York, the North Woods in Maine, offer stamping-ground for the purpose; but to those who would wander among the high mountains, the far-off ranges of the West afford the only hope. The question of a vacation is to the physician a very practical one, both for himself and for his patients. We do not, therefore, hesitate to occupy a few pages in calling the attention of our readers to the far Northwest and its advantages. Moreover,

this region probably presents a very favorable locality for the out-door treatment of consumption, although its claims and advantages seem hitherto to have been overlooked.

Western Dakota is in the northern portion of the dry belt which runs through the United States. It is similar in climate to Colorado, but differs from that State in not being distinctly mountainous, and in its plains not being highly elevated above the sea. There are certain cases of consumption in which the dry, cold air of Colorado acts beneficially, although the latitude and the consequent rarefaction of the atmosphere are trying to the patient. There are as yet, neither in Western Dakota nor in Montana, unless in a few towns, proper facilities for the care-taking of invalids, and for a person in the advanced stage of consumption to attempt to face the hardships of ranche-life would be absurd. The opportunities for occupation in Dakota, and still more in Montana, are, however, at present very good, and we would direct persons in the incipient stages of consumption to these Territories for permanent location. Montana contains numerous ranges of mountains, but its inhabited places are rather in the plains, and most of them are of lower altitude than are the Colorado resorts. The winters of Montana are also tempered by the so-called Chenook winds, which, blowing from the west, are at once so mild and dry that they lap up the snow and in a few hours leave bare the whole country.

In Dakota blizzards are more to be feared than in Montana, and the Chenook winds are less frequent and pronounced, although the inhabitants of Western Dakota claim that these reviving winds do reach them. Any person with feeble lungs settling in Dakota must either provide for staying in-doors during the existence of blizzards, or for living in the so-called Bad Land Country. The Bad Lands stretch over a wide amount of territory, running north and south some hundreds of miles, with a breadth of fifty or more miles east and west. They are composed of innumerable bluffs of earth two or three hundred feet high, fantastic in form, some conical, some truncated, some with broad tops, separated by narrow gulches, or, more rarely, by meadows a few hundred yards in width, but always so closely approximated that under their shelter cattle and people are almost as protected from the wind as within four walls. Last winter in the Bad Lands the thermometer fell as low as 60° below zero, but owing to the protection from the winds and the dry-

ness of the atmosphere this intense cold was so little felt that a calf dropped on Christmas-day, and left without shelter or any care, is not only healthy but has well thriven, and the manager of the ranche told us that only on three days had he found an overcoat necessary in riding.

In 1806, John Coulter left the Lewis and Clarke expedition to go to the Missouri River to hunt and trap. Escaping from the Black-foot Indians, he lived for some time with the Bannock Indians, and in 1810 returning to St. Louis, gave an account of wonderful spouting springs and boiling caldrons which he had seen in the Rocky Mountains. By this he acquired a great local notoriety as the chiefest of modern liars, and the locality which he described was derisively spoken of by hunters as "Coulter's Hell." In 1844 one James Bridger penetrated to the locality described by Coulter, and on his return was no more believed than had been his predecessor. It was not until 1863 that the first credited description of the region now familiar as the Yellowstone Park was given by Captain De Lacy. The more recent history of this wonderful country is now known of by all men. We do not propose to inflict upon our readers any description of it at all, but only to say that after having wandered over the greater part of these United States except the California region, there are, in our opinion, only two places that are worth the trouble of getting at them: one is Niagara Falls, and the other the Yellowstone Park. Possibly the Mammoth Cave might be added to the list. The wonders and beauties of the Yellowstone can scarcely be exaggerated.

The amount of hot water that is going to waste in the Yellowstone region is sufficient to fill the heart of a Chinese laundryman with an agony of sorrow, and to make an American sanitarian look with pity and disgust upon the small springs of Arkansas and upon the rest of the world with profound contempt. There are in the Park simply thousands of hot springs of all magnitudes,—some mere pellucid pools, some trickling fountains, some spouting masses of water almost sufficient to supply a city. And it can scarcely be otherwise than that in the future some of these springs will be found to possess very valuable medicinal properties.

Generally speaking, most of the springs can be divided into two sets,—the calcareous or calcic and the silicious. The Mammoth Hot Springs is the most important of the calcareous waters. It is really a large collection of

springs, which, commingling with one another, have by their conjoint effort deposited a mountain of carbonate of lime. Two of these springs have been analyzed by Dr. Henry Leffmann, of Philadelphia, with the following results. (See U. S. Geological Survey, 1878, part ii. page 389.) The Cleopatra Spring, water strongly alkaline, temperature 154°.

Grains to imperial gallon.	
Sodium chloride.....	13.496
Sodium sulphate.....	35.504
Calcium sulphate.....	13.587
Calcium carbonate.....	24.850
Magnesium carbonate.....	7.455
Silica .....	3.500
<hr/>	
98.392	

Spring No. 17. Temperature, 165°. This may be arranged as follows:

Grains to imperial gallon.	
Sodium sulphate.....	34.370
Sodium chloride.....	18.900
Calcium carbonate.....	17.920
Magnesium carbonate.....	2.170
Silica.....	3.360
<hr/>	
76.720	

A greater number of the Yellowstone springs are silicious, and deposit immense masses known as geyserite, which contains ninety per cent. of silex. An analysis of one of these, the Opal Spring, a silicious water in the Gibbon Geyser Basin, by Dr. Leffmann, gives the following result:

Grains to imperial gallon.	
Sodium chloride.....	82.180
Calcium sulphate.....	3.220
Silica .....	53.760
Calcium chloride.....	4.060
<hr/>	
143.220	

The analysis of the Jug Spring of the Fire-Hole Geyser Basin resulted as follows:

Grains to imperial gallon.	
Sulphuric acid.....	1.400
Chlorine .....	19.180
Silica.....	14.560
Calcium.....	Traces
Sodium.....	34.440
<hr/>	
69.580	

These analyses show that the springs of the Yellowstone are rich in mineral matter. But they do not fairly represent the resources of the region. Many of the waters are certainly strongly alkaline, and the immense masses of sulphur which are to be found in certain portions of the Park, as well as the deposits around many of the springs, show that these

waters are, some of them, also strongly sulphurous. The so-called Sulphur Mountain is a large butte full of small crystalline deposits of sulphur, and with sufficient sulphur emanations coming up through which to make liquid deposits upon the warm ground at the top,—drops of melted sulphur, which might well be spoken of as drops of golden dew.

A member of the United States Geological Survey told us that one of the springs is very rich in boric acid, and that a number of them contain a notable percentage of arsenic. Near the Mammoth Hot Spring is a lake of warm water in which the invalid might well disport himself for hours; suiting the temperature to his needs by shifting his position towards or away from the thermal springs which feed the waters.

The only place that we know of in the Northwest which is at present prepared for the treatment of disease by the use of water and bathing is that which is known as Hunter's Springs. This is situated a few hours of railroad riding this side of Livingston, near the Yellowstone River, whose rapid waters would afford for the invalid much amusement in the taking of large trout. There are three or four distant springs which furnish a very abundant supply of water both for drinking and bathing purposes. The hotel, which is just finished, is primitive but sufficient. There is a large bathing pool which reminded us forcibly of that at the famous baths of Luck in Switzerland, besides numerous bath-tubs, and all necessary arrangements for private bathing. The heat of the main spring is 168° F., and it has a specific gravity of 1.03 at 60° F. No analysis of it has ever been published, but we are enabled to give an original analysis made by Prof. Lehnen, of St. Paul:

	Grains to imperial gallon.
Solid contents.....	21.76
Magnesium carbonate.....	3.35
Ferrous carbonate.....	.16
Calcium carbonate.....	1.65
Potassium chloride.....	2.10
Sodium chloride.....	.15
Potassium sulphate.....	1.68
Sodium sulphate.....	1.38
Magnesium sulphate.....	7.07
Calcium sulphate.....	2.01
Alumina and silica.....	2.21
	<hr/> 21.76

The amount of solid matter in the Hunter's Spring water is not very great, but there are more salts than are contained in the Hot Springs of Arkansas, and it is probable that syphilitic, rheumatic, and skin affections could

be very successfully treated by it. The spring already enjoys a considerable repute in the Territory of Montana, and at the time of our visit there were some eighteen or twenty people undergoing treatment.

Before the thermal springs of the Northwest can attract invalids from distant places much greater development must certainly take place, and we strongly urge upon the Northern Pacific Railroad authorities the policy of furthering such development. It would certainly pay the railroad, then, to have a thorough exploration of the springs of the Park made at their own expense. The United States government, however, as owner of this property, ought to develop it.

Attached to the present United States Geological Survey there should certainly be a chemist, who should have a sufficiently well-furnished laboratory in the Park to make careful studies on the spot of a large number of these innumerable hot springs. At present there are no facilities in the Park for the reception or care of health-seekers, although there are large general and well-managed hotels, and to them sanitariums could readily be attached.

#### ON THE USES OF IODOFORM IN VENEREAL DISEASES.

THE employment of iodoform in the treatment of venereal affections, though advocated as far back as in 1857 by Von Maitre, did not attain any repute with the profession until the disclosure of the eminent antiseptic virtues of the drug created a new and rationally founded base for its therapeutic exhibition. The fall of the previously excessively high price of the drug taking place about the same time aided of course no little the growing popularity of the remedy.

A decade or more having passed since the general introduction of iodoform into the therapeutics of venereal diseases, a critical review of the results of its clinical trials obtained thus far will be a study both timely and instructive.

Dr. Max Brockhart, treating of the same subject in the *Monatshefte für Praktische Dermatologie*, No. 1, 1886, has collected all pertinent literary material with such care and painstaking, that no abler guide could be selected for our discussion. We cannot, of course, view any other aspects of the proposed subject than those pertaining directly to the therapeutic practice. The following

divisions recommend themselves for convenience' sake :

I. Iodoform in the treatment of gonorrhœal affections.

II. Iodoform in the treatment of soft chancres and buboes.

III. Iodoform in the treatment of syphilis.

#### I. IODOFORM IN THE TREATMENT OF GONORRHOËAL AFFECTIONS.

Watson Cheyne\* in 1880 first proposed iodoform as an application in gonorrhœa. He employed iodoform bougies made from cacao butter, with the addition of eucalyptus. This author claimed that by allowing the bougie to remain in the urethra for four to five hours daily, and by using astringent and antiseptic injections besides, the gonorrhœal inflammation could readily be controlled in seven to ten days. Campana† recommended in the first stage of an acute gonorrhœal urethritis an injection consisting of 6 dr. of iodoform and 3 grains of carbolic acid in 3 oz. of glycerin and 1 oz. of water. The researches of Mandl, Tarnowski, Keyes,‡ and Bockhart, however, could not verify the observations of Cheyne and Campana, and it soon became a therapeutic maxim that iodoform exerted not the slightest favorable influence over gonorrhœal inflammations of mucous membranes. Indeed, Bockhart even ascertained that a gonorrhœa of females treated exclusively with iodoform lasted longer than the cases treated with the usual disinfectant and astringent solutions.

Gonorrhœal epididymitis has also and even sooner than gonorrhœal urethritis been treated with various preparations of iodoform. Alvares proposed in 1877 the iodoform ointment, later Kurz the glycerite of iodoform, and finally Pape and Fischer the iodoform plaster. All of these authors claim to have obtained satisfactory results with iodoform in epididymitis, though Bockhart's experience could again not confirm them.

In erosions and ulcers of the cervix, however, such as are apt to follow a chronic gonorrhœa, iodoform, as all authors agree, renders the best of services. Dr. Wolf, of Würzburg, has the merit of having established a method of applying iodoform in these lesions which, in simplicity and promptness, surpasses all others. He fills little gauze sacks of the size of a chestnut with finely-pow-

dered iodoform, and places them on the seat of the affection, where they are retained for twenty-four hours by means of cotton tampons. Previously the vagina, especially its cervical portion, is carefully washed out with two per cent. solutions of carbolic acid. Thus treated, even large erosions and ulcers disappear often in two to three weeks. To summarize, then, the first portion of our discussion, we may say that iodoform is of no service whatever in the treatment of gonorrhœal inflammation, but can claim for it a curative influence over ulcers and erosions of the cervix.

#### II. IODOFORM IN THE TREATMENT OF SOFT CHANCRES AND BUBOES.

Isard§ and Lazansky|| claim the credit of having first called attention to the advantages derived from iodoform in the treatment of soft chancres. Isard laid particular stress upon the fact that the new remedy produced no pain by its application, and that compared with the formerly used means, its action was prompt and quick. He employed iodoform both as powder and in form of suspension in alcohol and glycerin (iodoform, 45 grains, alcohol, 2½ dr. ; or, glycerin, 1 oz.), the former in superficially seated ulcers, the latter when cavities or concealed regions were to be reached. Lazansky introduced still another form of its application, viz., an ethereal solution (1 : 15 to 30), which is especially eligible when a protracted irrigation,—as in phagedenic ulcers of the anus,—is desired. Tarnowski noted that, under the influence of the iodoform treatment, the ulcers rarely assumed a phagedenic¶ nature, and that by the rapid elimination of the specific detritus the danger of auto-infection was materially lessened. Nearly all observers agree that treated with iodoform the soft chancre loses in about two weeks its contagious character and enters the stage of reparation. In small chancres a strong ethereal solution, applied three times daily, will give the best results ; in larger ones, Unna's ether-spray or the powder-dressing\*\* recommend themselves. Unna and Bockhart declare that the ethereal solution of iodoform, providing the ulcer with a suitably thin layer of the drug, gives better results than the powder itself. In soft chancres sit-

¶ Or diphtheritic.

\*\* Changed every twenty-four hours.

\* *Brit. Med. Journ.*, 1880, and *Lancet*, 1882.

† *La Salute*, 1883.

‡ *Journ. of Cut. and Ven. Dis.*, 1883.

uated in the phimotic prepuce, Isard's suspension of iodoform in alcohol and ether, as stated above, is a choice application in phagedenic or diphtheritic ulcers; the powder is preferable, and in chancres located in the urethra iodoform bacilli are indicated. The introduction of Unna's grated iodoform-mull into the therapeutics of the soft chancre (*vide Monatshefte für Praktische Dermatologie*, 1884, p. 242) deserves an especial mention as a decided progress in the technique of dermatological practice. To epitomize the above, we may assume from the exceedingly rapid and favorable action of iodoform upon all kinds of soft chancres that the drug is a specific against the virus of the soft chancre. At least it is certain that no other drug, if it be salicylic acid, resorcin, or nitrate of bismuth, can even approximately be compared with iodoform in healing effects upon the soft chancre. We can also add that these effects do not refer to the mechanical absorbent action of the powder-dressing, for other powder-dressings, such as those of nitrate of bismuth or oxide of zinc, do not have the same curative influence. We are compelled to believe in a chemical influence of the iodoform upon the virus of the soft chancre.

In the therapeutics of suppurating buboes resulting from soft chancres iodoform claims the character of a sovereign remedy. Isard and Petersen\* even credit the drug with abortive or preventive virtues regarding this suppurative inflammation, the former employing for the purpose iodoform ointment, the latter iodoform collodion. Still, this abortive power attributed to iodoform is not universally acknowledged. Very certain, however, is it that suppurating buboes under the iodoform treatment heal twice as rapidly as under the old forms of treatment. Under an exactly applied iodoform dressing, and strict observance of antiseptic precautions, the opened bubo never becomes phagedenic, diphtheritic, or chancrous in nature.

The principal methods of applying iodoform in suppurating buboes deserve to be especially alluded to:

1. Lazanski puts iodoform into the disinfected wound, and applies cotton lint (charpie), caoutchouc-paper, and a roller-bandage over it, changing the dressing every twenty-four hours.

2. Martini employs precisely the same method, with the addition of scraping the wound with the sharp spoon.

3. Petersen's plan is undoubtedly the most perfect one. He employs what is known as the occlusion-dressing, adding pressure to the dressing, as stated above. In this dressing flannel bandages only are used. With a perfectly fitting occlusion-dressing the patient is well able to walk about with impunity.

Hence the conclusion to be arrived at from the foregoing statements is that iodoform is an unexcelled remedy in suppurating inguinal buboes, and that it is best applied by the plan proposed first by Petersen.

### III. IODOFORM IN THE TREATMENT OF SYPHILIS.

Iodoform has been tried partly as a substitute for mercury by those opposed to the mercurial treatment of syphilis, and partly in place of iodide of potassium in the treatment of the tertiary forms of syphilis. The estimation of various observers of the value of iodoform as an antisiphilitic remedy varies materially. Von Maitre recommended first its internal use in syphilis, and claimed that 45 grains could be ingested daily with impunity. Davenport† gave it in secondary syphilis, together with iron. Lazanski gave daily to twenty syphilitic patients (tertiary form) six to eight pills each, consisting of  $1\frac{1}{2}$  grains of iodoform, and pronounced the action of the drug very efficacious. Moleschoff,‡ likewise, eulogized iodoform in syphilis, and called attention to the fact that this drug is much more slowly eliminated from the economy than mercury, and is for this reason therapeutically more active than the latter.

Other authors, however, like Zeissl, Strokowski, Tarnowski, and Mracek, after careful and numerous observations, have come to the conclusion that iodoform given alone internally in syphilis is but little reliable and useful. It is to be added that the drug causes certain secondary symptoms, such as gastric disturbance, vomiting, an acne-like eruption, and nervousness, rendering its exhibition practically ineligible. Although the percentage of iodine contained in iodoform is much larger (ninety-six per cent.) than that contained in iodide of potassium (seventy-six per cent.), it is, nevertheless, possible to introduce into the system by the latter drug in a short time far greater quantities of iodine than by the former. Besides, iodoform cannot be taken with impunity in larger daily doses than 15 grains, while of iodide of potassium much greater quantities are well borne.

† *Boston Med. Journ.*, 1873.

‡ *Wien. Med. Woch.*, 1878.

\* *Monatshefte*, 1883, No. 10.

The results obtained with subcutaneous injections of iodoform, as proposed by Bozzi in 1870 and Thomann\* in 1881, are sufficiently satisfactory to engage our interest. The latter employed the glycerite of iodoform (6 to 20), and iodoform dissolved in oil of almonds† (0.3 to 6), using as an average dose as much as 12 grains of iodoform. Both in recent and in tertiary syphilis these authors obtained very gratifying results, 3 to 4 dr. of the drug being required for the cure of tertiary lesions. The local reaction after injections of iodoform is immaterial; the pain soon passes away, as do the induration and redness of the place of injection. An abscess has been recorded in only a single instance. Neumann used besides glycerin still other vehicles for his subcutaneous injections of iodoform, such as ether (1 to 6), castor oil (1 to 15), and ether and olive oil (5 aa).

Neumann found by experiments on animals that from the glycerite of iodoform  $\frac{1}{3}$  grain of iodoform, and of the ethereal solution  $\frac{2}{3}$  grain of iodoform were resorbed daily. In a case where Mracek had given in thirteen days  $1\frac{1}{2}$  dr. of iodoform, he noted the elimination of the drug in the urine for a period of forty days. In another case, Thomann found iodine in the urine forty-three days after the last injection of the glycerite of iodoform. These observations demonstrate that the glycerite of iodoform applied subcutaneously acts similarly as calomel applied hypodermically: from the drug deposited into the cellular tissue small quantities are being constantly and for a long time dissolved, and enter the circulation. This peculiar action of iodoform renders the drug particularly eligible in the light tertiary forms, while in the grave gumous processes, necessitating the rapid introduction of larger quantities of iodine, iodide of potassium, being more rapidly and in greater quantities resorbable, is far preferable. In conclusion, the beneficent action of iodoform in syphilitic neuralgia is to be mentioned. Daily doses of 15 grains of iodoform, taken in pill form, are regarded as a promptly-acting remedy.

To resume the above, we find iodoform as an antisyphilitic remedy inferior to iodide of potassium, surpassing the latter only in syphilitic neuralgia. Employed subcutaneously, however, the drug, especially in the light tertiary forms, produces a far more constant and

effective an action on the organism than iodide of potassium.

#### THE PHYSIOLOGICAL ACTION OF IODOFORM.

Our knowledge of the physiological action of iodoform has in the last few years been materially enriched by the labors of Prof. Binz‡ and other German observers. Let us review in brief the essential features of the physiological action of the drug. Placed upon an ulcerating surface, iodoform is gradually dissolved by the fatty substances present in that locality, and liberates iodine in presence of oxygen and light or of oxyhæmoglobine and living cells. It is to the thus continually generated free iodine that the antiseptic and antibacterial virtues of iodoform are to be ascribed. The action of iodoform upon the blood-corpuscles is a very singular one: it prevents their emigration from the blood-vessels by paralyzing the protoplasm of the blood-cells, and besides, prevents the formation of giant-cells. The analgesic effects of iodoform upon ulcers are explained by Binz as being due to a paralysis of the axis cylinder of the exposed nerve termination produced by the liberated iodine. The iodine enters also the juices of the body and associates with their albuminous constituents, the thus formed albuminate of iodine being, however, soon decomposed into an iodide and an iodate. In tissues of an acid reaction (the cortex of the brain and gastric mucous membrane) iodine regains its former state of integrity, and again reacts upon the cells of the part. This explains the partly irritating and partly depressing influence of iodoform upon the cervical cortex and its tendency to provoke serious gastric disturbances. Experiments made upon animals revealed fatty degeneration of the heart, the liver, and the kidneys as the result of the action of iodoform. Even after the ingestion of large quantities of iodoform, the resorption from the intestinal tract is very limited as compared with the resorption proceeding from granulating surfaces and wounds. In the urine iodoform appears as an iodide and an iodate. This elimination proceeding, however, very slowly, the action of the drug upon the economy is evidently a prolonged one.

We cannot conclude our discussion without

‡ Binz and Möller, *Über das Iodoform und über Iodsäure*, *Arch. f. exp. Path.*, 1877; Binz, *Toxicologisches über Iodopreparate*, *Arch. f. exp. Path.*, 1880; Binz, *Virchow's Archiv*, 1882, vol. lxxxix.; Behring, *Über Iodoform Intoxicationen*, *Deutsche Med. Woch.*, 1882.

\* *Centralblatt für die Med. Wiss.*, 1881.

† Solutions of iodoform are to be preserved in a dark bottle, else iodine will be liberated, and applied hypodermically will prove highly irritating.

referring with a few words at least to the intoxication phenomena, as occasionally recorded after the application of iodoform. In the first place we mention the acne not rarely observed after the internal and subcutaneous employment of iodoform, resembling closely the acne produced by the internal use of iodide of potassium. Besides this acne a peculiar exanthematous dermatitis is often observed after the external application of the drug, especially in presence of a certain predisposition on the part of the patient. This eruption is readily cured by a dressing with argillaceous earth, or with a two per cent. solution of carbolic acid in alcohol. Grave cerebral intoxications, such as frequently described by surgical writers, occur but rarely in the treatment of venereal affections, unless it be in presence of the idiosyncrasy mentioned above. Besides, iodoform is no longer used in such large quantities as was practised in the past. Oberländer\* reported two grave intoxications with iodoform which deserve to be noted. Two syphilitic patients, who had received 10 dr. of iodoform in eighty days, *i.e.*, 75 grains in seven days, showed threatening cerebral symptoms, such as coma and collapse, which persisted for a long time, and finally passed away.

To disguise the repulsive odor of iodoform many agents have been proposed, among which we mention cumarine, the tonga-bean, the oil of peppermint, the oil of bitter almonds, Peruvian balsam, Muscat balsam, tannic acid, and recently pulverized roasted coffee.† This agent being itself an antiseptic, and incorporable with iodoform in any proportion, is undoubtedly the safest, as it is the most effective of all substances recommended for the disguise of the odor of iodoform. If the chancrous ulcers of the penis are treated with Unna's grated iodoform plaster-mull, the taste of the drug is easily disguised by fixing a layer of odorized cotton (with cumarine) over the plaster.

#### ON ANTIFEBRIN, THE NEW ANTIPYRETIC.

FROM Prof. Kussmaul's clinics at Strasburg Drs. Cahn and Hepp send the good news of the discovery of a new and great antipyretic into the professional world. We abstract from the *Centralblatt für Klinische Medicin*, August 14, 1886, a *résumé* of the properties and action of antifebrin.

\* *Deutsche Zeitschrift für Praktische Medizin.*, 1878.

† Opler, *Centralblatt für Chirurgie*, 1885, No. 30.

"A happy incident," the authors say, "has placed in our hands a preparation which was found to possess excellent antipyretic virtues." A chemical examination proved the drug to be a long-known chemical body which owns the formula of  $C_6H_5NHC_2H_5O$ , and belongs to the group of phenylacetamides or acetanilides. It was prepared as far back as 1853 by Gerhardt (*Annalen*, lxxxvii. 164), by the action of aniline upon acetylchloride or anhydrous acetic acid. Antifebrin is a white, crystalline, and odorless powder, slightly pungent, almost insoluble in cold water, sparingly soluble in hot water, but readily so in alcohol. It melts at  $113^{\circ}C$ , and distils unchanged at  $292^{\circ}C$ . It owns neither acid nor basic properties, and strongly resists the majority of reagents.

Numerous experiments on dogs, guinea-pigs, and rabbits have convinced the named observers that the drug can be ingested in relatively large doses without provoking any toxic symptoms, differing in this respect materially from aniline ( $C_6H_5NH_2$ ), with which it is chemically closely allied. The temperature of normal animals is not influenced by the drug.

Cahn and Hepp have tried the new antipyretic in the following twenty-four cases :

	Cases.
Typhoid fever.....	8
Erysipelas.....	5
Acute articular rheumatism.....	2
Pulmonary phthisis.....	4
Abscess of the lungs.....	1
Fever in leucæmia.....	1
Pyæmic fever.....	1
Septicæmia.....	1
Pneumonia migrans.....	1

The remedy was given in single doses of 4 to 15 grains, stirred up in water, dissolved in wine, or enclosed in wafers.

The maximum dose given in twenty-four hours was 31 grains. The proper size of the single dose cannot, as in all antipyretics, be determined *a priori*, but depends upon the type, the gravity, and stage of the affection. It is safe to regard 4 grains of antifebrin as equal to 16 grains of antipyrin, regarding time of appearance, duration, and magnitude of the antipyretic action. Consequently it will be seen that antifebrin, however scantily soluble, acts as quickly, and four times stronger, than antipyrin. As yet the drug has never failed in the hands of the Strasburg clinicians.

The following illustrates the mode of distribution of the new remedy in several cases, and at the same time allows of a comparison with antipyrin regarding antipyretic power.

*Typhoid Fever. Workingman, aged 19 Years.*

7 " .....	39.6° C.	38.6° C.	.....	.....	.....
8 " .....	.....	.....	36.8° C.	38.7° C.	37.9° C.

As seen from this table, the antipyretic action of antipyrin sets in about one hour after its exhibition, reaches its maximum after about four hours, and passes off in from three to ten hours, according to the dose employed. In doses sufficiently large to reduce a high febrile temperature to the normal status or even lower, the apyrexia persists usually four to eight hours. The fall of temperature is accompanied by reddening of the skin and moderate perspiration.

In the reascent no rigors were ever observed, though in some instances the patients had—as after the use of antipyrin—sensations of cold. Simultaneously with the fall of temperature, the observers noted a considerable

reduction in the frequency of the pulse and an increase in the arterial tension.

The gastro-intestinal tract bears the new remedy undoubtedly well, for in no instance was there any nausea, vomiting, or diarrhœa observed. In several cases, on the contrary, the improvement of appetite following the use of the drug\* was quite apparent.

Notable were also in a number of cases the great thirst of the patients and the profuse diuresis appearing during the period of apyrexia. No patient complained about the med-

\* In all probability due more to the relief brought by the apyrexia than to any especial action of the drug on the digestive tract.

icine, and the general subjective state of health was quite favorable during the use of it. In one of the cases of rheumatism antifebrin caused a prompt relief from very troublesome pains in the joints. The only symptom which at first startled the experimenters was a peculiar cyanosis appearing in some patients on the face and extremities, which appeared and disappeared simultaneously with the apyrexia, without causing rigors or any other symptoms. In some instances the patients grew somnolent during the apyretic period.

Besides the advantages above alluded to, viz., prompt action in small doses, absence of secondary symptoms, and comparatively slight transpiration, the new remedy commends itself also on account of its cheapness.\*

It is theoretically interesting to find that this antipyretic belongs to a chemical group wholly different from that which includes the other antipyretics, which are either phenols (carbolic acid, hydrochinon, resorcin, salicylic acid), or belong to the chinoline order (chinolin, kairin, antipyrin, quinine, thallin).

Antifebrin is a neutral body, far removed in chemical composition from either of these groups.

#### KOLA NUT.

WE have in several previous issues of the GAZETTE called attention to the action of the kola nut, and a paper recently published by Dr. N. Hudson (*Med. Times*, June 26, 1886) still further encourages more definite trials of this remarkable agent. Dr. Hudson reports a case of intermittent and irregular heart's action, with dyspnœa and faintness, occurring as a consequence of endocarditis in a rheumatic subject, in which the use of about 150 grs. of kola paste, taken once or twice a day, in hot milk, prepared like chocolate, caused great relief. The heart's action became more regular, dyspnœa and faintness disappeared, and the violent headaches to which the patient had been previously subject were prevented. The employment of the kola seemed to be satisfying to the appetite, and the bodily weight increased from ninety-eight to one hundred and five pounds. No marked change was observed in the character of the urine, the quantity voided being somewhat increased, but the total quantity of urea excreted remaining at 10 or 12 grammes daily. The ac-

tion of kola is generally attributed to the caffeine which it contains, but Dr. Hudson states that in this case both caffeine and convallaria had been employed without success, while the action of digitalis was only temporary and palliative.

#### NOTE ON HYPNONE.

URETHAN, Jaksch's discovery, announced last year with so much *éclat* and auspicious anticipation, has been unable to establish itself in the faith of the profession, and it is little likely that the coveted sanctum of any Pharmacopœia will ever open itself to a remedy of so uncertain and unreliable a nature. Hypnone, the successor of urethan, appears to be no luckier than the latter. It has figured in the medical journals for some time, was complimented on its felicitous name, and—"the rest is silence."

Hirt and Moebs, of Breslau, went to the expense and trouble of instituting exhaustive experiments with hypnone, giving the drug in as large doses as 7 grains, and were naturally rather grieved to find the results obtained wholly negative, especially in view of Jaksch's loud claims as to the virtues of the drug. The experimenters write to the *Breslauer Artslische Zeitschrift*: "The results obtained with hypnone were in every instance positively illusory, and the drug ought to attract no more attention from the profession."

The above sentence will no doubt be condemned by other observers, but it seems as if the drug is doomed to oblivion.

#### THE NEW EDITION OF DR. FLINT'S PRACTICE.

WHEN a medical book has been the chief guide for many years for the practitioners of at least one continent, its fate upon the death of its author becomes a matter of general concern. Usually the book falls into the hands of an editor. Occasionally the man selected has sufficient nerve and ability to swallow the book, assimilate it, and send it forth with the stamp of his own personality blending with and overriding that of the original author. Under these circumstances the work becomes a new book, and may be endowed with a life for another generation. Usually, however, the editor prunes, interjects, and variously alters the old favorite, so that it becomes like a tree which has not

\* Kalle & Co. sell a moderately pure article for thirty marks per kilogramme.

grown by the physiological process of interstitial deposit, but has had grafted on it here and there a new limb, and finally produces an abundance of discordant fruit. Such an alteration of a great medical classic is a woful mischance : ruinous to the reputation of the original author ; misleading to the rising youth of the profession. As Dr. Austin Flint, Jr., however much of fame he may have achieved in other lines, is not known as a clinician, on reading the announcement of a new edition of his father's *Practice of Medicine* we had greatly feared that the book would be found to have suffered at the hand of some alien editor. It is, therefore, with great pleasure that we learn that Dr. Austin Flint himself completed the revision of the book before his death. We trust that the sale will be both extensive and rapid, and the volume in its perfected form will be widely placed upon the shelves of our readers as the monumental life-work of its great author. We also hope that in the future the publishers will take care that its shapeliness is not defaced by editorial chisellings or bracket-enclosed excrescences.

According to our thinking, Dr. Flint was not a man of genius, although endowed with good judgment and excellent powers of reasoning. A man of marked ability, but not of originality, he achieved by infinite painstaking labor. It is stated that the basis of his practice was an unbroken series of records of cases, in private practice and hospitals, begun in 1833 and continued until his death. The mere manual labor of writing the sixteen thousand nine hundred and twenty-two folio pages of manuscript was not a little thing. And it is said that these pages are all in Dr. Flint's own handwriting.

---

## Reports on Therapeutic Progress.

---

### *THE PHYSIOLOGICAL TREATMENT OF CHOLERA AFTER SEMMOLA.*

We abstract from a recently published work of SEMMOLA ("Nuove Ricerche terapeutiche sul Cholera Asiatica")—in which this well-known Italian clinician has laid down the clinical and therapeutic experiences gathered during the recent Italian epidemic of cholera—his views on what the author calls the "physiological treatment of cholera." Semmola holds that no cure can ever be expected from any medication directed specifically against the comma-bacillus, and also warns of too

heroic a therapeutic interference with the symptoms of the premonitory and the algid stages.

A physiological treatment, in the judgment of the author, is one which is directed towards raising the vital energy of the body, so as to endow the same with a higher power of resistance against the disease without injuring the entire system by the biochemical action of pharmacal agents.

The main features of this treatment are the following :

1. Absolute rest of the affected organs—viz., the gastro-intestinal tract—by observing a strict fasting on appearance of the first diarrhoea stools. As long as the diarrhoea persists no food whatever is to be taken. Over six thousand clinical observations in Naples have shown that even 5 to 6 teaspoonfuls of bouillon, given prematurely (*i.e.*, before the stoppage of the diarrhoea), sufficed to reproduce the gravest symptoms, such as algidism and asphyxia. After the disappearance of diarrhoea and vomiting, milk may be given in very small quantities.

2. Timely excitation of the physiological powers by therapeutic or, rather, by physiological means. The best of these are undoubtedly repeated warm baths. To prove beneficial the baths must, however, be given in the first period of the disease, before any sign of algidism has set in. The application of the warm bath in cholera has been in vogue also in former times, but never yielded any benefits, as it was only employed in the algid stage of the affection. The warm bath is not alone useful, as was held formerly, on account of the supply of heat to the cold surface of the body,—a mere physical process,—but also and particularly on account of the physiological influence it exerts on the economy. The warm bath excites the peripheral nervous system, and at the same time, by reflex action, the centre of circulation. The consequence of this excitation is an harmonious restoration of the functional physiological relations between the surface of the body and its internal apparatus, especially those of the digestive tract. True, this biological process can only be realized in the first stage of the disease, when the biological relations between the superficial and internal organs have not yet been essentially altered or broken off altogether.

Through diaphoresis the bath favors besides the elimination of toxic substances from the system, which by affecting the various nerve-centres cause ominous alterations in the se-

cretory, vaso-motoric, and general oxidation processes. If necessary, the bath can be repeated every one to two hours. After the bath the patient is to be wrapped up in woollen blankets, and is to be given warm aromatic and weak alcoholic drinks. It is well to give also small doses of opium (laudanum, liqueur de Batteley, chloridine), in order to render the nervous centres less susceptible for the toxic principles and in order to reduce the increased intestinal secretion. Opium, given at the proper time, aids and supplements the physiological treatment.

#### ON IODOL, THE NEW ANTISEPTIC.

Two recently-published papers on iodol, one by G. SCHMIDT ("Das Iodol, ein neues Antisepticum," *Berliner Klinische Wochenschrift*, 1886, No. 4), and the other by FR. PAHL (*Untersuchungen über Iodol, Diss.*, Berlin, 1886), disclose some additional facts in reference to this new antiseptic agent. Schmidt employed iodol at the university clinics of Heidelberg in the following forms: 1. As a powder, applied to the wound like iodoform; over it a compress of argillaceous earth is fixed. The iodol formed no scab with the secretion, the secretion itself was odorless, the granulations abundant, and the healing of necrotic ulceration-surfaces satisfactory. 2. As a solution, 1:16 alcohol + 34 glycerin, intended for tampons in carcinomata of the uterus and rectum, also for injections in fistulas and ulcerative cavities. 3. As iodol gauze.

Schmidt expresses himself thoroughly contented with the results obtained with these various modes of iodol application, and lays particular stress upon the absence of all intoxication phenomena in the use of the new antiseptic. He believes, however, that the granulations obtained from the use of iodoform are more luxuriant than those appearing after the employment of iodol.

Pahl, who conducted his researches on iodol in the Pharmacological Institute at Berlin, commends, likewise, the use of iodol, especially in view of its "comparatively slight toxic qualities." His experiments made with iodol on various animals invite our particular interest. If large doses are given to animals, Pahl says, the animals grow emaciated, and ultimately perish through general weakness. The post-mortem examination reveals invariably fatty degeneration, especially of the liver and kidneys. Iodol is almost totally decom-

posed in the organism, and is eliminated as an iodine alkali through the urine. Pure iodine appears never in the urine after the use of iodol.

#### PULSATILLA.

According to M. BRONEVSKI, in *L'Union Méd.*, anemonin, a substance prepared from the *anemoni pulsatilla*, first irritates, then paralyzes the respiratory centre. It diminishes cardiac activity and voluntary movement by its action on the spinal nerve-centres. It causes death in dogs and rabbits by paralyzing the heart, in doses of 3 grms. of the extract administered subcutaneously. This quantity corresponds to ten of infusion or decoction and to one to two of the tincture. 0.1 grm. of anemonin proved fatal to a rabbit in an hour; dogs succumbed to a subcutaneous injection of 2 grms. in from twenty-four to thirty-six hours, with increasing dyspnoea, torpor, paralysis of all the limbs, diarrhoea, and cessation of cardiac movement. Autopsy showed hyperæmia of all the parenchymatous organs. Therapeutically, anemonin is useful in bronchitis, convulsive cough, and asthma. The daily dose is from 0.05 to 0.1 grm. taken twice in powder. A larger dose causes headache and heaviness in the limbs.—*Med. Press*, August 11, 1886.

#### THE CAUSE OF THE TOXIC ACTION OF CHLORATES.

From the *Archiv für Experimentelle Pathologie and Pharmacologie*, vol. xxi. p. 169, we abstract some conclusions of DR. STOCKVIS on the poisonous action of chlorates, which, for the sake of their novelty, invite our interest.

The doctrine held heretofore, that the chlorates exert an oxidizing, and consequently decomposing, influence upon the living blood, is no longer tenable. The toxic action of large doses of chlorates refers solely to their action as salts.

If the chlorates were actually reduced in the living organism, the urine would necessarily present a deficit in the quantity of eliminated chlorates. True, a slight deficit in the chlorates has always been determined in the urine, but it must be remembered that a small portion of the chlorates passes unchanged into the saliva, and, besides, the elimination of the chlorates in the urine is not yet ended in twenty-four hours, the urine voided later always containing some more

chlorate. It has also been determined that the urine, on standing for some time, reduces a chlorate into a chloride.

Chloride of sodium materially increases on the day of its ingestion the quantity of the chlorides in the urine, while the chlorates are present in their maximum quantity.

After the withdrawal of chlorates the elimination of chlorides decreases simultaneously, although the urine still contains some chlorate. The increase in the elimination of chlorides is wholly independent from the quantity of ingested chlorates; it is, for example, just as large after 15 grains as after 30 grains.

This increased elimination of chloride of sodium refers by no means to a reduction of chlorates, as is demonstrated by the following example: Of two rabbits who were starved until their urine contained no more chlorine, one received 60 grains of chlorate of sodium and the other 60 grains of nitrate of sodium. These two salts caused a relatively great and almost equal elimination of chloride of sodium, which disappeared on the following day.

Another evidence against the reduction is the fact that even very small quantities of chlorates pass into the urine unchanged. It is only outside of the body in experiments with blood, in autopsies, etc., that this reduction of chlorates actually takes place. Of the chemical constituents of the animal organism none is able to reduce chlorates outside of the body at the temperature of the blood; the urine itself, though, is, as intimated above, well able to reduce chlorates.

Having thus shown that the reduction of chlorates is not the cause of the toxic action of these salts, the author passes to the discussion of what constitutes this cause. He found experimentally that chlorate of sodium exhibited by intravenous injection is not more and not less poisonous than the ordinary table salt, and that hence the latter could, with equal propriety as the former, be called a poison. The lethal dose was for both salts 8 to 10 grammes per kilogramme of body weight. The phenomena, after the injection of salt, were at first irritation, then depression of the central nervous system, albuminuria, and œdema of the lungs. The chloride of potassium appeared strangely to be even more poisonous than the chlorate of potassium.

The "toxic gastritis" usually found after poisoning with chlorate of potassium is the result of the introduction of a large quantity of an irritating salt into a mostly empty stomach, and the high-graded dyspnœa, the deep cya-

nosis, the cardiac weakness, and the convulsions are partly reflex phenomena emanating from the toxic gastritis, and partly refer to the action of potassium, or that of a concentrated solution of salt on the blood.

The author gives, in conclusion of his paper, the following practical suggestions: The chlorates ought not to be given in too large quantities at once, and not in too concentrated a solution (one and one-half to two per cent.), nor on an empty stomach. The average dose for an adult may reach 2 drachms *pro die*. If the urinary secretion is scanty, for one reason or another, the chloride of sodium is preferable to the chloride of potassium, as the slower elimination of the potassium salts may in these cases easily lead to an intoxication.

In connection with this paper, we find the mentioning of a case of poisoning with chlorate of potassium with a lethal termination. A man took by mistake 4 drachms of the drug in two hours, and died in twelve hours.

#### THE PHYSIOLOGICAL ACTION OF MENTHOL.

DR. GOLDSCHIEDER, at a meeting on April 9, of the Physiological Society of Berlin, discussed the action of menthol on the sensory nerves. It was well known that it produced on the skin a sensation of cold, which was commonly ascribed to evaporation. On the other hand, the same sensation, when produced in the mouth by solutions containing menthol or peppermint, was explained by a supposed astringent effect. Dr. Goldscheider had come to the conclusion that neither of these explanations was correct. He made his experiments with a solution of menthol in lanolin, which he rubbed into circumscribed regions of the skin. After the rubbing, the thermometer showed, in all such places, an increase of temperature to the extent of 2° C., notwithstanding the marked sense of cold produced. The hypothesis of evaporation was excluded by the fact that the feeling of cold was no less marked when the part rubbed was covered with a watch-glass, and could, therefore, be produced only by direct stimulation of the nerves of sensation of cold. Again, if of corresponding places on the forehead, where these nerves are most abundant, one were rubbed with the menthol ointment, and the other not, bodies which previously had caused no particular sensation would be felt as cold on the former spot, but not on the latter. Dr. Goldscheider, observing that

while some regions, as the forehead, were especially sensitive to cold, others, as the elbow and the volar side of the wrist, were so to heat, found that the inunction of these with menthol produced a sensation of warmth, though less striking than that of cold in the former regions; and he called attention to the recent communication of Professor Herzen on the precisely analogous results of pressure on the nerve-trunks in these regions respectively. He therefore concluded that the sensations, in some places of cold, and in other places of heat, produced by menthol, were purely subjective and consequent on the direct stimulation of the special nerves of temperature, those usually cognizant of cold being far more sensitive to its influence than were those adapted to receive impressions of higher temperatures.—*Brit. Med. Journ.*, August 21, 1886.

#### IODOL.

Among the many new antiseptic remedies that recently have been introduced into surgical practice, iodol is among the most likely to retain its place. Iodol, or the powdered iodide of pyrrol ( $C_4I_4NH$ ), is a light fawn-colored micro-crystalline powder, odorless, and almost tasteless. It contains 88.9 per cent. of iodine. It is soluble in warm oil, 1 to 7; alcohol, 1 to 3; and ether, 1 to 2; and also in chloroform. It has been used powdered as an application to phagedenic chancres and for syphilitic sore throat, and Dr. Foy (*Med. Press*, August 4, 1886) has also made it into bougies with cocoanut oil for cases of gonorrhœa and gleet, and as an ointment with lard (1 to 3) for indolent ulcers. In fact, it may be used with success in all cases where iodoform is indicated. It is non-poisonous, and is eliminated from the system as iodine. Dr. Wolf has found from his experiments made on rabbits that a ten per cent. solution in oil produced no irritation. Drs. Mazzoni and Rocci have employed it over two hundred times.

In venereal affections (chancres, adenitis, and periadenitis) it was used with the best results. The venereal sore having been washed with water, and carefully dried, was sprinkled over with iodol powder, and covered with silk protective; if the chancre was large and very purulent, Brun's wool was also employed; this dressing was repeated every twenty-four hours. After the dressing had been renewed from four to six times, the base of the chancre commenced to granulate, and the edges showed a tendency to cicatrize; no

fresh ulcerations, nor any adenitis in the inguinal region, ever appeared, and even commencing inflammation of the lymphatic glands (in two cases) subsided without any special treatment.

In patients who came with wounds which had large openings, with thinned, undermined, and blue edges, the free incisions which are recommended in such cases should be avoided, and the surface of the sore simply sprinkled with iodol powder. In twenty-four hours a change was noticeable in the character and quantity of the secretion. The ulcer was cleansed with Brun's wool, and, after the dressing had been renewed three or four times, it commenced to granulate, and showed a tendency to rapid cicatrization.

In ulcers where there is very marked necrobiosis, the good effect of iodol is very remarkable,—the foul smell disappears, the secretion diminishes, and the ulcer changes in a short time to a healthy granulating wound. In atonic ulcers also the result was likewise favorable: even after two applications a distinct improvement was to be observed. On the other hand, iodol was quite ineffectual in sloughing ulcers where there were marked sloughs; in these cases its use had to be discontinued, since not only did no improvement ensue, but the disease extended. The cause of this seemed to be that the iodol in such cases is washed away by the fluids which are secreted in such quantity, and that in employing alcoholic solutions the iodol is precipitated and then carried away.

As regards the principle of the action of iodol, it is probable that, as in the case of iodoform, very small amounts of iodine are constantly being liberated at the place where it is applied, and that on this the local therapeutic effect of the remedy depends. The nascent condition of the iodine seems to render possible the further combinations to form iodide of potassium and iodide albuminate, under which condition it is absorbed. The liberation of the iodide from iodol, especially when this is in the form of iodol gauze, may be more certain than in the case of iodoform. Iodol gauze dressings show, after remaining on for a single day, a distinct separation of iodine in the gauze, and also a marked brown coloration in the neighborhood of the wound; very probably this liberation of iodine is occasioned by the warmth of the body, though possibly also by a fermentation occasioned by the secretions from the wound. That the former plays a part may be seen from the fact that iodine is liberated when iodol gauze is

heated in a test-tube, and also a development of iodine may be observed in the gauze when it is kept at a temperature of 39° C. for twenty-four hours on a water-bath.

Although iodoform is far from being perfection as an antiseptic,—for on account of its very slight solubility in water, 1 in 500, and also on account of its present high price, many would prefer another drug,—nevertheless we cannot refuse to admit the great advantages of its mildness of action, its power of deodorizing secretions, the absence of the formation of crusts, and its being almost completely free from odor. The greatest advantage would also accrue if, in addition, its employment should be unattended with any poisonous results.

Like most medicinal agents, iodoform has been recommended as a local application to cancer, especially uterine, and as a powder it has been insufflated on the diseased surface, and its glycerin alcohol has been painted over the carcinoma.

#### ICHTHYOL IN CHRONIC URTICARIA.

We abstract from the *Wiener Medicinische Blätter* of August 5, 1886, the following therapeutic note regarding ichthyol :

According to UNNA, we possess in the salicylate of sodium and in atropine two remedies against chronic urticaria, which are ordinarily wholly reliable. Still, there are cases in which not only these drugs but the entire host of nervines fail, and ichthyol alone brings relief and cure. The following two cases may serve to illustrate this fact :

1. Miss S., æt. 22, chlorotic ; presented for treatment March, 1885, for an extended urticaria, existing four weeks. Salicylate of sodium was given in the largest doses for several days without the slightest benefit. Atropine internally (0.0005 *ter die*), painting with equal parts of spir. saponat. and tinctur. bellad., decoction of valerian, and iron pills brought on an improvement, which, however, soon disappeared again. Ichthyol (pure) taken in 5-drop doses three times daily, and applied also externally, established a perfect and lasting cure.

2. Vigorous man ; treated by other physicians without success for an urticaria of several weeks' standing. Unna prescribed ichthyol, to be employed internally and externally, and again effected a perfect cure.

In neither case did any relapse appear.

#### THE ACTION OF URETHAN.

DR. EMILE KRÆPELIN contributes an article to the *Neurologisches Centralblatt* (March 1) on the action of urethan. The reports on this hypnotic have up to the present been uniformly favorable. Kræpelin's experience has been of a like character. He has given the drug in about two hundred instances. Most of his cases were cases of insanity, but thirty-four instances of various other diseases were included. The dose ranged, as a rule, from 1 to 3 grammes ; occasionally a dose of from 4 to 5 grammes was given. No unpleasant effect on the heart or nervous system, either during the action of the drug or afterwards, was ever noticed. In one case of alcoholic gastric catarrh, vomiting was produced by the larger dose. The appetite, however, was never in the smallest degree impaired, even by the continuous use of the drug for several weeks. Urethan acts as a genuine hypnotic. Ten or fifteen minutes after taking it a quiet sleep comes on, which lasts for several hours, and from which the patient wakes up without any unpleasant feeling about the head. Should the sleep be interrupted by any external cause, the patient generally falls off to sleep again as soon as the disturbance is removed. The certainty of the drug's action depends upon the cause of the sleeplessness, and on the dose. It is not a hypnotic of great energy, and in cases of great excitement it is of little value. In such cases it is far inferior to paraldehyde. In delirium tremens, especially, it failed. Perhaps, however, if larger doses were given in these cases, the result might have been more satisfactory. For the relief of pain the author does not consider it of any use whatever. In cases of phthisis the combination of a small quantity of morphine was found useful. When given in doses of 1 gramme, it acted sufficiently in fifty-four per cent. When the dose was 3 grammes, the result was favorable in seventy per cent. The form of mental ailment, in most cases, was general paralysis or melancholia. In the excited stages of general paralysis, small doses were frequently altogether without effect. The larger doses in such cases gave a satisfactory result in sixty per cent. of the cases. In the higher degrees of excitement, in mania, for example, as well as in delirium tremens, the author found himself obliged to have recourse to paraldehyde. In melancholia the drug gave better results ; it secured quiet sleep in seventy-seven per cent. The patients were all women, and many of them were very anæmic. Among the most

favorable indications for urethan the author places exhausting diseases, feverishness, and lowered nutrition. One great advantage which this drug has over paraldehyde is that it is not so unpleasant to the smell or taste, and it can, if necessary, be taken in simple solution without any flavoring or disguising agent.—*Brit. Med. Journ.*, September 4, 1886.

#### RHUS RADICANS.

SEÑOR FERNANDO ALTARNIRANDO, writing in the Mexican journal *El Observador Médico* on a plant called locally the Guau or the Mala Mujer, the scientific name of which is *Rhus radicans*, states that its active principle is of a peculiarly volatile nature, and relates the case of a man who, after collecting and cutting the plant up, complained of chills and a feeling of extreme fatigue, and subsequently developed a rash, at first erythematous, and afterwards pustular, affecting chiefly the groins, axillæ, and other parts where the sudorific glands are most numerous. The action of the exhalation from the plant could not well have been direct, as the parts chiefly affected were covered with clothes, and so the writer suggests that the active principle must have entered by the respiratory passages, being then carried by the blood to the skin, where its action became manifest. He advises that preparations of the drug should be made from the freshly-cut plant and its juice, and that all the collecting should be done before sunrise. The tincture might be made use of, but the extract must necessarily be inactive, as, indeed, it has proved itself, having been experimented on by Dr. Dominguez. In case of accidental poisoning, such as in the patient mentioned, the indications would be to produce diaphoresis, and to maintain the skin in a state of moisture. In order to prevent toxic effects, those who gather or manipulate the plant should be careful not to breathe the air which has passed over it, but should keep to windward of it.—*Lancet*, July 27, 1886.

#### THE VALUE OF RESORCIN, ICHTHYOL, AND LANOLIN IN CUTANEOUS DISEASES.

At the recent meeting of the American Dermatological Association, DR. H. W. STELWAGON, of Philadelphia (*Boston Med. and Surgical Journal*, September 16, 1886), read a paper with the above title, of which the following represents his most important conclusions:

Resorcin in eczema is rarely of benefit, but possesses some power over the itching. For this purpose a six per cent. ointment is useful. In greater strength it is irritating. In tinea sycosis it has proven of some value in ten to twenty per cent. strength. In tinea tonsurans, it is inferior to the remedies usually employed. In one case of leg ulcer healing took place under its use. In a second case, no effect was produced. In seborrhœa and alopecia dependent upon this disease, a lotion, consisting of a drachm of resorcin, one or two drachms of castor oil, five minims of Peruvian balsam, and four ounces of alcohol, was of value. In tinea versicolor it was found less useful than a solution of hypophosphite of sodium. In psoriasis and in one case of lupus erythematosus, the result was negative. In one case of superficial epithelioma, a fifty per cent. ointment produced a good result. In a second case, a fair result was obtained, and in a third the result was negative. In a case of favus, a twenty-five per cent. ointment used two months produced no decided effect.

*Ichthyol.*—In a small proportion of cases of rosacea and acne vulgaris a ten to twenty per cent. preparation was found beneficial. In eczema it was valueless and usually irritating. In furunculus it acted with good results in three cases, when applied as a twenty per cent. plaster. In the fourth case it had no effect. It was of service in psoriasis, and also in a case of lupus erythematosus. In favus it was used without effect.

*Lanolin.*—In some cases as an ointment base this is superior to the ordinary fats in use. Where a simple protective action is desired, it is inferior to vaseline, cold cream, or lard. In chronic cases, where there is infiltration, and a degree of penetration is the object, lanolin is especially valuable. The writer stated that, according to Liebreich, a *lanolinum purissimum* was now manufactured, in which the cholesterin ethers were absent. The main disadvantage of lanolin, as now manufactured from sheep's wool, is its strong sheepy odor. In a few acute and subacute cases of eczema, lanolin, for some reason, proved irritating. As a rule, however, it is bland and unirritating.

#### COCAINE IN THE TREATMENT OF GONORRHOËAL OPHTHALMIA.

MR. A. LEAHY reports in the *Indian Medical Gazette*, July, 1886) two cases of gonorrhœal ophthalmia, in both of which the greatest benefit was derived from the local

application of cocaine. As is well known, in gonorrhœal ophthalmia it is of primary importance to lessen the inflammation rapidly, to relieve the intense congestion of the conjunctival vessels and reduce chemosis, and by so doing prevent ulceration and sloughing of the cornea. Last, but not least, is the relief of the ocular and circumorbital pain, which, by its persistence, greatly depresses the patient, and prevents sleep. Mr. Leahy employed a mixture composed of  $\frac{1}{2}$  grain of sulphate of atropine, and 4 grains of sulphate of cocaine incorporated with 100 grains of vaseline. This mixture was introduced beneath the upper eyelids, and after three days' treatment the chemosis rapidly became less, the discharge diminished in quantity, the pain completely disappeared, and the cornea, which had been hidden by the chemosis, became visible.

#### LIGATION OF THE VERTEBRAL ARTERIES FOR THE RELIEF OR CURE OF EPILEPSY.

The question of the value of surgical interference in the treatment of epilepsy is one that has never been fully settled. It is true that where depressed bone is found as the cause of the epilepsy, no one at the present time questions the necessity of relieving the pressure, but the operation of ligating one or more of the large vessels furnishing blood to the brain for the relief or cure of epilepsy is a procedure concerning which opinions are at present at wide variance. But few cases have been reported where this operation has been performed for epilepsy, so that as yet scarcely any sufficient and reliable conclusions can be drawn. From a study of these cases, however, DR. J. L. GRAY thinks that the following conclusions are warranted (*Neurol. Review*, July, 1886):

1. Ligation of the vertebral arteries should take its place as a recognized procedure in the treatment of certain cases of epilepsy.
2. The operation should be confined to those cases in which the exciting causes of the attacks come from some region outside the brain.
3. The arteries should be tied as high up as practicable, and the ligature should include all the fibres of the sympathetic accompanying the vessel.
4. Where the side of the brain which is first invaded by the disease can be determined, the artery of that side should be ligated.

5. Where the invasion of the disease is apparently bilateral, both vertebrals should be ligated.

6. This operation should not be done as a substitute, but as an aid to other forms of treatment for the relief or cure of epilepsy.

#### COLD APPLICATIONS TO THE PRÆCORDIA IN FEVER.

In the *Practitioner* (August, 1886) DR. F. T. GRIGOROVICH publishes the results of this mode of treatment of fever employed in the Rostoff Military Hospital. His observations were made on uncomplicated cases of typhoid fever. He finds that the respiration, at first somewhat quickened and rendered irregular by the reflex actions, subsequently becomes slower. At the end of the application of the ice and the next morning it is deeper and more regular, but somewhat slower than before the ice was applied.

The general conclusions regarding the effect of applying cold to the region of the heart are as follows:

1. The cold undoubtedly reaches the heart itself, and thus produces an effect on its action.
2. This effect is particularly noticeable when the cardiac beats are increased in frequency in consequence of a high temperature quickly attained, and where a certain degree of sensitiveness to a high temperature exists.
3. The effect of cold is not marked at the end of a prolonged attack of fever, pathological changes having by that time probably become established in the cardiac muscle.
4. The local application of cold is only capable of protecting the heart-muscle from the effects of a high temperature when it is applied assiduously from the commencement of the disease.
5. Under its influence the action of the heart improves, the number of beats diminishes, while their force and amplitude increase.
6. Cold applied to the region of the heart diminishes the gravity of the *typhoid* condition and favorably influences the respiration.
7. With regard to the effect of cold applied to the region of the heart on the course of the general temperature, the author cannot at present express a decided opinion, as he did not investigate the question; but in the results which he obtained indications may be found of the possibility of its causing some diminution of the temperature.

*A NEW METHOD FOR THE DETECTION OF HYALINE CASTS.*

DR. S. E. ARMSTRONG, of Passaic, N. J., sends to the *New York Medical Record*, September 4, 1886, a description of a method of manipulation devised by him to facilitate the detection of hyaline casts in the urine. He calls attention to the value of these casts from a diagnostic point of view, since the presence of albumen alone is no certain evidence of the existence of nephritis, and its absence does not necessarily imply a healthy state of the kidneys. He writes: "The hyaline cast may be said to form the stroma of all other varieties,—the oily, epithelial, granular, etc. It is always found in some of the different stages of any of the forms of Bright's disease, particularly in the first stage, when a recognition of the trouble is most to be desired. The propriety of making a positive diagnosis on the strength of this one sign may justly be questioned, but there are usually other symptoms, objective or subjective, to aid us. Of course the use of the microscope in the search for hyaline casts is an absolute necessity. Two methods are usually taught, viz., staining and tilting the mirror. The first I regard as impracticable, because it involves too much trouble; the second because it is unreliable. I have never been able to make the desired success of either, though I must confess that I have not frequently tried the former. There is another method which comes to me in the nature of a discovery. Others may have known of it for years. I have not been able to find a description of it in the books, although it may be there. Briefly, it consists in preparing the specimen in the usual way, between a plain slide and cover-glass. Then placing the slide in position and adjusting the focus, the observer, with his eye at the instrument, presses the cover-glass down with a thumb on either side of the objective, and then, the slide being held firmly by the clips, pushes the cover-glass a little bit forward and back. By this means he has the advantage of *looking for an object in motion*; also, a cast, if present, is made to pass, rotating on its long axis, through different planes of the fluid, *hence through different possible foci*. By this means alone it is almost sure to be discovered. But there is still another advantage in this method, viz., as the cast revolves through the liquid it gathers on, perhaps, amorphous urates, vibriones, or whatever minute object it comes in contact with, and is thus brought out into bold relief. Of course we must by previous

examination exclude granular casts, otherwise, *after* manipulation, we may be puzzled to tell which variety we have discovered; we must also be sure we have not rolled out a white blood- or pus-corpuscle, so that it misleads us into the belief that we have found a short one of either one or the other variety. Prolonged manipulation is neither necessary nor advisable."

*SUBLIMATE INJECTIONS IN GONORRHOÆAL CYSTITIS.*

The history of an obstinate case of gleet and cystitis is given in *El Dictamen* by SEÑOR GARCIA ANDRADAS, which, after being treated unsuccessfully by means of injections of nitrate of silver, yielded very quickly to injections of corrosive sublimate. The patient, who was a river fisherman, contracted gonorrhœa, which was treated for a month with balsams and astringent injections. The discharge then became serous, and exquisitely painful vesical tenesmus supervened, the calls to urinate being so frequent as to give the man no rest. An attempt to pass an instrument occasioned the greatest agony when it came in contact with the prostatic portion of the urethra. The diagnosis made was that of acute prostatitis consequent on gonorrhœa, and so the local application of a sublimate solution appeared to be the most rational treatment, as it had in the author's hands proved very beneficial in cases of subacute cystitis due to the same cause; but it was thought well to try first Guyon's treatment. With great difficulty, owing to the extreme sensitiveness of the urethra, an elastic catheter was passed to the prostatic portion, and ten grammes (160 gtt.) of a one per cent. solution of nitrate of silver injected. A few minutes afterwards urine was passed with great pain, so a warm bath and an opiate were ordered, which gave only temporary relief, the opium having to be repeated at night. The next day the patient's condition was the same as it had been before the injection. Three or four days afterwards a similar injection was given, with no better result. Four days later, as there was no improvement, the use of sublimate injections was commenced. The catheter was passed as far as the prostate, and forty-five grammes of a two per mille solution of sublimate in warm water were injected. This the patient was compelled to retain for three minutes; the subsequent micturition was very painful, but at night he was able to rest, and retained his urine for three hours. The next day the

urine was less turbid, and it was voided less frequently. His condition continued to improve for three days, when a second sublimate injection was given of double the quantity of solution. This occasioned some pain, but it quickly passed off, and the patient was able to rest. In four days' time he requested to be discharged, as his urine was clear, and he had no pain on micturition. Thus, the author remarks, two injections sufficed to cure completely an affection usually most obnoxious to treatment of an ordinary kind. The superiority of sublimate injections has shown itself in several cases of a somewhat analogous character in which he has employed it. These he proposes to publish and discuss on some future occasion.—*Lancet*, August 21, 1886.

#### ACORN COCOA IN THE TREATMENT OF DIARRHŒA AND VOMITING IN CHILDREN.

Acorn cocoa is a preparation of ordinary cocoa powdered and freed from fat, to which are added the soluble parts of roasted acorns without cellulose, and a little sugar and roasted flour. Liebreich suggested this combination, and that it should be tried in the treatment of diarrhœa and vomiting of children, and it was found that of one hundred and two cases of diarrhœa with vomiting six only died, and the remainder recovered in from one to eight days. This combination is now manufactured as a substitute for tea, coffee, or cocoa, and is refreshing, tasty, and nutritive even for adults. DR. F. W. ELSNER (*Australasian Med. Gazette*, June, 1886) has also had a considerable experience with this remedy in this class of cases, and has obtained marked success by its use. His mode of administration was to mix a teaspoonful of it with cold water in a small cup, and then to boil it, constantly stirring, and this quantity is administered thrice daily by means of a spoon or feeding-cup. All other food and medicine is prohibited, and the quantity may be gradually reduced. Dr. Elsner has notes of twenty cases of continuous and exhausting diarrhœa with persistent vomiting, which had continued for three weeks in two cases and for shorter periods in the others. In half the cases various remedies had been employed before the acorn cocoa was administered; in the others, however, it was the first drug given, and its effect was rapid and complete in each instance, and it never took more than two days to bring about improvement, while twelve days

was the outside at which a complete cure was effected.

#### PIPERINE IN INTERMITTENT FEVER.

DR. C. S. TAYLOR reports in the *British Medical Journal*, September 4, 1886, two cases of intermittent fever which were treated by the administration of 3 grains of piperine every hour until 18 grains had been taken, as soon as perspiration commenced to follow the malarial paroxysm. On the following day, when the intermission was complete, the same quantity was directed to be taken every three hours. According to Dr. Taylor, this treatment in every case succeeded in checking the paroxysm. As soon as this is accomplished, he advises the use of the following pill, whose employment has always seemed to be very beneficial:

R Blue mass, gr. 1;  
Piperine, gr. 2;  
Sulphate of quinine, gr. 3;  
Syrup, q.s.

#### Reviews.

STUDIES IN PATHOLOGICAL ANATOMY. By Francis Delafield, M.D. Vol. II., Part 2.  
New York: William Wood & Co., 1886.

The above issue of Dr. Delafield's Studies contains descriptions and plates of chronic pulmonary phthisis and lobar pneumonia.

In regard to the nature of chronic phthisis, Dr. Delafield gives his opinion in very positive and unmistakable terms. He writes, "The one essential feature of chronic phthisis is the presence of tubercular inflammation; without this there is no phthisis. Such a tubercular inflammation is not only an essential but also a primary part of chronic phthisis; it exists from the very commencement of the disease. Phthisis is not an ordinary form of chronic inflammation of the lung, to which tubercles may or may not be added; it is primarily a tubercular affection." While tubercular inflammation is considered the essential and primary lesion of chronic phthisis by Dr. Delafield, he, however, admits that it may be very slight, or so changed by age, or other forms of inflammation may be so developed, as to obscure the tubercular character of the lesion. No doubt the confusion which exists in regard to the nature of this disease is in a great measure owing to the many complications that may arise during the progress of the disease. Notwithstanding some doubt

may exist in reference to the exact nature of the affection, it is gratifying to be assured by Dr. Delafield that "the lesions, the symptoms, and the treatment of chronic phthisis often depends much more upon the associated inflammations than upon the phthisis." The tubercle-bacilli are mentioned as being "regularly found associated with the lesions of chronic phthisis." The rôle played by these organisms, whether they are the cause or simply a result of the tubercular inflammation, is not here discussed by Dr. Delafield.

The different lesions which may be associated with chronic phthisis are represented by twenty-two drawings. Diffused hepatization of the lung is pictured in its various stages by nine drawings. This lesion is said to consist in the inflammatory products which fill the air-spaces, or by the growth of tissue in the walls of the air-spaces, or by a combination of both these conditions.

The morbid changes which are met with in the larynx, trachea, and bronchi in chronic phthisis, are illustrated by eleven drawings. Three drawings are given of the miliary tubercle, which is believed by Dr. Delafield to be always present in chronic phthisis, and also that it presents the same characters as the miliary tubercle which is observed in acute phthisis and in chronic miliary tuberculosis. Four drawings representing a rare form of lobar pneumonia are given. This special lesion is said to be "characterized by the production of new connective tissue within the cavities of the air-spaces a few days after the invasion of the inflammatory process." That organized tissue may be found in cases of lobar pneumonia which have been chronic in their course has been pointed out by a number of observers, but the cases given by Dr. Delafield are acute in their nature, and the pathological changes found after death differ from those met with in ordinary lobar pneumonia in that the exudation into the air-spaces takes on immediate organization, instead of following the usual course of later becoming connective tissue or being absorbed.

The drawings which illustrate Dr. Delafield's work are, as in the previous volume, made with high magnifying power, and therefore appear truly gigantic. Whether there is any advantage gained by the employment of such high power in studying ordinary pathological lesions is an undecided question with us. No doubt there is much minute detail still to be studied out in the histological elements of most pathological changes, but an examination of the drawings of Dr. Delafield

does not teach us any new arrangement of structure, since a comparison of his pictures with those of other illustrators, who have not used such high power, shows an exact resemblance between them. The author, however, has drawn faithful and most beautiful illustrations. Such work cannot but aid in the study of pathological changes, and we hope the "Studies in Pathological Anatomy" will continue to appear.

## Correspondence.

---

### LONDON.

(From our Special Correspondent.)

The event that has been exercising the professional mind in England during the last few weeks is of course the annual meeting of the British Medical Association at Brighton. As one of your most worthy representatives happily and forcibly puts it, the specialization of the medicine of to-day demands co-operation: it is only by co-operation and association that the centrifugal elements of medical science, as they are now pursued, can be made to take a centripetal course at periodical intervals, and thus true inductive advance secured. Some of us may be of opinion that this very sound principle is carried too far, or even sacrificed, when association is made to take the shape of "collective investigation," for individuality is then sunk, and the observer becomes the slave of a committee, who demand the formulation of experience and opinion under a few cut-and-dried heads of their own choosing. In this country medical science, like our medical institutions, has been mainly supported by "voluntary contributions," and collective investigation does not appear to be in a very thriving condition at the present time. But it is quite a different matter that men should meet periodically and submit to mutual discussion the problems that have been holding their attention during the interval. It is good, too, that some of our aspiring juniors should have an occasional opportunity of raising their voices, premature though some of the conclusions may be which they air upon the platform. Nor must we forget the overworked practitioner, who welcomes his annual "outing," this relief from harassing work, this occasion for meeting old friends and of enjoying some social dissipation of a very innocent kind.

Brighton was the meeting-place this year, as I have said. Your readers, remote though

most of them be from the Sussex coast, have all heard of the queen of English watering-places. Few towns present greater attractions of a kind, especially to country associates, who would enjoy the keenest air in England, the brilliant sea, the gay crowds on pier and parade, and the many successful efforts to afford them pleasure in the way of dinners and balls, which a fashionable place like Brighton affords. I trust our foreign friends were equally satisfied. For ourselves, we, who live in the metropolis, do not as a rule take kindly to Brighton: it is too London-like to afford us the kind of change which our brains require. I need hardly add that the hospitality of our Brighton *confrères* was hearty and universal, and that all of us welcomed our visitors from America and the Continent. Among the members of the profession from your side of the Atlantic were Dr. Nathan S. Davis, of Chicago; Dr. Billings, of Washington; Dr. Grant, of Ottawa; Mr. Kingston, of Montreal; Dr. Shoemaker, of Philadelphia; Dr. Blake, lately of California; Dr. W. Brodie, of Detroit; Dr. Covernton, of Toronto; Dr. Pancoast, of Philadelphia, and many more. France sent us two worthy representatives in the persons of Brown-Séquard and Charcot; and German pharmacology had a splendid exponent in Oscar Liebreich.

I will not dwell upon the great "set" addresses, nor on the remarks with which the presidents of the various sections opened the work in their several departments. I must, however, refer to Dr. Billings's most able and original oration in "Medicine," which was so eagerly anticipated that it certainly of itself attracted some of the members from a distance. Dr. Billings's address was constructed with a literary skill, and given with a character and force which delighted his audience. It did more than this, however. It opened our eyes on this side to the vastness of the movement which is going forward with you in the States; to the rare and unique opportunities which you possess of studying certain great disease problems with respect to racial and other factors; and to the glorious future that your profession has before them, when medical education and medical legislation shall have become more advanced.

Dr. Broadbent's opening address in the Section of Medicine on the "Remote Effects of Remedies," was worthy of a man who is fast rising into the very first rank of London consultants. It was essentially the outcome of ripening experience,—an experience gained

by laborious observation and a far-seeing but carefully-tempered philosophical mind. Instead of joining in the cry against treatment, which is only too fashionable with us at present, Dr. Broadbent devoted his most recent deliverance to the abuse of useful remedies,—to the evil effects which frequently flow from the ill-considered application of treatment, whether medicinal or dietetic, to purchase present relief regardless of future consequences. The science of therapeutics can only profit by such a timely outspoken warning; for therapeutics suffers as much from the contempt brought upon useful methods by their indiscriminate use as from the studied neglect which it receives at the hands of its direct opponents. What could be nearer the truth than these remarks of Dr. Broadbent's upon a vaunted class of remedies for asthma, which we owe to the United States, and of which "Nimrod's cure" is the type: "The bronchial spasm may be met by a remedy which satisfies the demand for a local stimulant or sedative; but the solanaceous drugs, of which the powders are largely composed, contain powerful alkaloids, which obtain direct access to the blood through the pulmonary capillaries, and produce their effects on the nervous and vascular systems; and when you see the stupefied mental condition and the congested face and eyes, and note the large, weak, sluggish pulse, showing paralysis of the arterial walls, it is clear that such effects cannot be indefinitely repeated with impunity. It is where there has been a catarrhal element in the asthma that the results have seemed to me most disastrous. The right ventricle loses its tone like the muscular coats of the arteries, and instead of becoming hypertrophied, yields to the resistance in the pulmonary circulation and is dilated, finally giving rise to systemic venous stasis and dropsy." Again, it would be well for some of our West End physicians to read these words on dieting and carefully weigh them: "Numbers of people, especially women, who suffer from pain in the epigastrium after meals, attribute the discomfort to some particular article of diet. It is not uncommon for the medical man to take the same view of the case, and a scale of diet is laid down with great minuteness, adopting all the sufferer's restrictions, and perhaps adding more. This may be done even when neuralgia is crying aloud for more and better blood to be sent to the nerve-centres. There is still discomfort and a sense of repletion after food, and the patient improves upon his instructions until

the starvation point is reached. The energetic wife and mother becomes a fretful invalid, and neuroses are developed unless acute illness supervene, during which liberal nourishment is insisted on. In all such cases it is not the food that disagrees with the stomach, but the stomach which disagrees with the food, and the proper treatment is not levelling down the nourishment to the digestive capacity of the stomach, but the bringing up of the functional energy of the stomach to the requirements of digestion by extra food of a stimulating character, by stimulants at meals, or by tonics."

Besides these subjects, Dr. Broadbent took up the evil remote effects of the habitual use of colchicum and other specifics in gout, the misapplication of the "Banting" process, and the heroic treatment of migraine, and dealt with them in words which are not likely to be lost.

But I must come to the Section of Therapeutics, in which the editors and readers of the GAZETTE will feel a special interest. The Section of Pharmacology and Therapeutics at the British Medical Association meetings is of but recent development, but it is already a thriving youngster. Along with the Section of Pathology it has relieved medicine somewhat of the crowd of papers annually presented for discussion. This year it met under the able and genial presidency of Dr. Lauder Brunton, the most prominent representative of therapeutical science south of the Tweed. Dr. Brunton's opening address was characteristic of the man. It was intended—and with complete success—not so much to adorn as to improve the occasion, to delight and charm less than to instruct his hearers. Which among us is not painfully conscious of the rapidity with which modern organic chemistry is marching away from us? We have struggled through one "notation" after another, and through more than one nomenclature; and all this only to find ourselves once more in the rear of chemical progress, which now appears to the uninitiated to be surely returning to cabalistic and alchemic symbols, when iodoform is represented by

and resorcin by an elaborate closed chain with lateral and terminal hooklets. Dr. Brun-

ton sympathizes with our difficulty in all this, and has given us an account of the connection between chemical constitution and physiological action couched in terms so plain and popular,—so full of easy illustration, and so suggestive,—that a child almost might master the elements of the subject. If his argument were not so continuous, I would have quoted freely from Dr. Brunton's admirable address; but, as it is, I will only cite a few sentences on certain benefits that have quite recently accrued from the study of this subject, leaving your readers to peruse the original text on other pages. It occurred to Dr. Brunton and Dr. Cash, in the course of a series of experiments, that if they could saturate the body of an animal with potassium they should be able to render it proof against the poisonous action of barium. Having met with some success, Dr. Cash pursued this line of investigation much farther, and obtained results which, in Dr. Brunton's opinion, are "among the most extraordinary and the most promising in pharmacology." Knowing, as he did, that corrosive sublimate was an exceedingly poisonous disinfectant, it occurred to Dr. Cash that it might be more harmful to disease-germs than to the bodies of higher animals, and that he might be able, by the introduction of the poison into the body of an animal, to render it unsusceptible to zymotic diseases. A similar idea had occurred to Koch, who injected corrosive sublimate into animals after previously inoculating them with anthrax; but his experiments failed, while Cash has proved successful by introducing the corrosive sublimate before inoculating with anthrax, and thus giving the drug the start of the disease. "These experiments," said Dr. Brunton, "acquire an additional interest from the fact that M. Pasteur, although uncertain regarding the exact mode in which his process of inoculation for hydrophobia has brought about such satisfactory results, is disposed to think that the agent which prevents the disease is a chemical substance and not a microbe."

The place of honor among the communications in the Therapeutical Section was very properly given to one by Liebreich, the discoverer of chloral, who read an important paper on lanolin, his new basis for ointments. Dr. Shoemaker, a recognized authority on the subject, took part in the debate. Two general discussions were well sustained,—the one on "Antipyretics," introduced by Dr. Carter, of Liverpool; the other, on "Analgesics," opened by Dr. Spender, of Bath. Among

the papers read were one by Dr. Shoemaker on "Hamamelis," which once more insisted on the value of the drug as a hæmostatic, spite of your own recent researches on its pharmacology; one by Dr. Blake, on the "Climate of California,"—a note of warning; the record of an investigation into the *modus operandi* of "Morphine in Diabetes," by Dr. Mitchell Bruce; and a preliminary communication by Dr. Semon and Mr. Horsley, on the "Action of Ether upon the Larynx."

August 21, 1886.

#### POTASSIUM PERMANGANATE IN AMENORRHOEA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—In the June number of the GAZETTE you ask for experiences as to uses of potassium permanganate in amenorrhœa. I have used it in two simple cases uncomplicated by anæmia, *without result*, giving two grains thrice daily, after meals, for six weeks, and using also stimulating pediluvia, and in one case local faradization of uterus for four weeks, three times weekly. In a third case I used it three weeks without any result in the same dose, and then resorting to other remedies for four weeks, the patient came all right.

My conclusion from this experience is that it is not so valuable a remedy in amenorrhœa as we have been led to expect.

Yours very respectfully,

J. N. TILDEN, M.D.

PEEKSKILL-ON-HUDSON.

#### THE ANÆSTHETIC REVELATION.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Allow me to recall attention to the article in your issue of August 16 by Dr. Shoemaker, entitled "Recollections after Ether-Inhalation." The paper is memorable in the interest of the topic and the guarded and conscientious spirit of its treatment; for what should have more interest, even for practical minds, than the fact, there repeated, that in so simple and easy an experiment as ether-inhalation the primordial mystery of being may be appreciated? and what should be more hopeful for the advantage of whatever of science may be involved than the fact of the experience being related by manifest gentlemen, whose tone carries conviction of reliability?

The illumination or insight to which that article refers has been usual with me for

twenty-five years. I published an account of it in 1874 in a pamphlet of thirty-two pages, of which I distributed one thousand copies gratuitously, and have never allowed it to be sold, nor any money to be made out of it by any one. My work had some attention, and elicited many communications, among them a remarkable letter from Alfred Tennyson, giving normal experiences of "a kind of trance to which he had been subject quite up from boyhood." This letter is even now, within a month, republished in English papers; and the topic of your article is an ordinary one to a very extensive circle both here and abroad, mainly of scientists of the order of speculative philosophy. The topic was considerably treated in *Mind*, the London metaphysical magazine, by Dr. Wm. James, the eminent metaphysician of Harvard University, he there endeavoring to *express* the secret. In that circle I am usually regarded as having first signalized the anæsthetic revelation as somewhat reliable and uniform in the experience of intellectual men; indeed, I published my work avowedly only for fear that the secret—that is, its apprehensibility—should die with me. Not but that thousands had experienced the insight, but that up to that time no one had publicly claimed it and demanded its uniform expectation. It will seem a very small matter to me to find myself mistaking the originality of so accidental a discovery, yet the discovery was treated as mine by the reviewers of that year. It is of much more interest and importance to me to have what was a lone-some secret to me for fourteen years confirmed as a homologous insight of the race, and seeking expression of its mystery whenever it appears to such as have appreciation of the difference between knowledge and mystery in our present stage of advancement.

But the general reader will be apt to lose patience with these extraneous considerations, and to demand the secret itself. It is but rational in any man, hearing the claim of a revelation, to expect to be told what it is. But here the race is wholly at fault as yet; for the secret clings to the condition, and is precisely that which philosophy has sought as abstract truth through all the history of thought. We can give the style and region of it, what it is generally about, but we fail to express it so as to recall it normally, simply through lack of "divine philosophy." We have not understood it expressibly, for the same reasons that we have not understood expressi-

bly anything at all in the region of thought to which it belongs.

To this part of the subject, which is now the main part to the advanced experimenters, Dr. Shoemaker's article is only initiatory. He declares the experience, and locates it in thought,—that is, he says it is the mystery of existence, or, in his own good words, "the simplest expression or essential nature of human existence;" it was given him *as* a revelation; he "must remember all that occurred," etc. But the questions, What is it? and Why was the whole illumination swept inexorably away from him? will be asked in vain until the philosophy of Hegel is rectified. I think I follow Dr. Shoemaker very well in his account. Of what he means by *aural waves* I know very well, but I think I may speak for myself and many others a doubt that a repetition of the experience would prove his lines to be a competent illustration. The fact that was impressing him was probably this. Sanity—our ordinary tenor and participation of intelligence—is felt, in the revelation, to be only one accidental or arbitrary grade or degree of a kind of humming which the anæsthetic hastens; this pace quickens until we lose all distinction, and as we "come to," and the pace slackens, we perceive that this high state was as true sanity as we ever had, and we are astonished at finding, as we land on our terra firma, that sanity is only an accustomed grade, that might as well be either higher or lower. So, in a less degree, a man, exhilarated with intoxicating drink, feels that he is only at his best, and some have wondered why one might not be born with "three sheets in the wind." It is here that interest culminates in the experience; as a certain amount of liquor makes a "better man" of him in his own true consciousness, does the anæsthetic legitimately quicken the thought up to the appreciation of the divine but impersonal mystery? Is that really the difficulty of philosophy,—the grasp of the truth of being,—that we are not quite quick-witted enough, rather than organically barred out from it? and is the anæsthetic revelation philosophy's goal?

Long experience has taught me the way to this awful mystery in the normal condition. I can lie on my back in the still night, and go as near to it as my nerve will sustainingly permit. To go farther would demolish individuality; a side glimpse is enough for a mortal eye. And I know philosophically the reason of this dread. The truth of us and of all being is duplex. Philosophy had got so

far with Hegel as to grasp the ancient saying that being and not being are equal, and halves of that reality which as a whole is being proper; but this whole could not be in time, and all dialectic involves a time process. The philosophical necessity was a new ontology, eliminating the element of time, and in which all things always are. This ontology is my claim to the attention of the hour.

I have gone as far as you can well accompany me as caterers to a "scientific" as distinguished from a metaphysical constituency. I may well wish that you would go farther; for all science, all absolute and radical explanation, is metaphysical; and in publishing the article of Dr. Shoemaker you essay positions which, however they may be "diagnosed" by physicians, as such, can be explained by metaphysicians alone. Referring facts to "law," "force," "designing mind," "divine power," and like generalities is no longer competent as for ultimate understanding.

If any of your readers care to follow my exegesis of the inevitable, they may consult the leading article of the last number of the *Journal of Speculative Philosophy* (D. Appleton & Co., New York, and Trübner & Co., London).

Much impressed by the tone and contents of the THERAPEUTIC GAZETTE, I trust earnestly in its success, and remain

Yours, with high regard,

BENJ. PAUL BLOOD.

AMSTERDAM, N. Y., August 31, 1886.

#### THE TREATMENT OF RHUS-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—It is my fortune every season to see quite a goodly number of cases of rhus-poisoning, and I wish to emphasize a plan of treatment for this annoying trouble, already mentioned by Dr. Morrow in the *Journal of Cutaneous and Venereal Diseases*, and copied in the GAZETTE.

My treatment is simply a saturated solution of bicarbonate of sodium. I saturate strips of muslin in this solution, and apply them evenly over the surface, and then endeavor to keep the surface thoroughly moistened with the solution until the dermatitis subsides. I do not give any medicine internally. There is nothing new about this plan of treatment, but it has been entirely successful in my hands in every case.

FREDERICK W. PUTNAM, M.D.

BINGHAMTON, N. Y.

## IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I desire to call the attention of the medical profession to the specific action of the oil of sassafras in rhus-poisoning. I have used this remedy for many years in these cases, and have never known it to fail in any case. I generally have the oil rubbed well *all* over the parts affected twice daily. Many cases do not require the second application. I also let the patient have from 3 to 5 drops on a lump of sugar three times a day. I claim that this will cure "*all cases*," no matter at what stage used. I have used the oil with perfect success after bicarbonate of sodium, sulphate of zinc, sugar of lead, and other usual remedies have completely failed.

It will instantly relieve the pain from the sting of any insect,—bee, hornet, or spider. It should be given internally in bad cases. It will abort boils and carbuncles if given in from 5- to 10-drop doses three times a day. Try it and report.

A. J. ROE, M.D.

DECATUR, ILL.

## IVY-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—If you are not already supplied with an abundance of prescriptions for ivy-poisoning, you may publish the following, which I have used for fifteen years without a single failure:

R Sodæ sulphis,  $\mathfrak{z}$ i;  
Acid. carbol.,  $\mathfrak{z}$ iss;  
Glycerin.,  $\mathfrak{z}$ ii;  
Aqua, ad q.s.  $\mathfrak{z}$ viii. M.  
Ft. sol.

Sig.—Apply on cloths, keeping them constantly wet with the solution.

No other treatment is required.

J. F. WHITE, M.D.

COUNCIL BLUFFS, IOWA.

## QUACKERY.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I would like to add a few words towards agitating what I consider a most vital question to every member of the medical profession, introduced in the last number of the GAZETTE by J. Z. Scott, M.D., of Scandia, Kansas. I sincerely hope that his remarks will strike every reader of the GAZETTE as favorably as they have me, and that the question will be agitated until the profes-

sion at large are thoroughly aroused to the fact that our business is being filched from us, to a greater or less extent, by a lot of quacks and charlatans, who are flooding the country with their nefarious nostrums.

It is astonishing to me how the profession have sat still so long, and seen this business going on right under their eyes, and have never raised their voices against it. I think, as Dr. Scott does, it is time, and high time, that we do something in the way of protecting our business.

Just go into any drug-store and see the shelves loaded down with these quack and proprietary remedies, read the advertisements of many of these venders, giving the names of a score of disorders their medicines will cure, ending up with, "This wonderful remedy is now recommended and prescribed by the leading men of the medical profession all over the world." Is it any wonder that our profession has no dignity in it in this country?

It is *true* that in nine families out of ten the physician is only called as the last resort. The many thousands and thousands of dollars which go in to make the coffers of these men fat, who have never spent a half-dozen hours in the legitimate study of medicine, of a right belong to the men who have spent years of hard labor and many dollars to fit themselves for an honorable calling.

There is another gigantic evil that the minds of the profession ought to be directed to, and that is the squelching of itinerant quacks. It is perfectly marvellous the cheek some of these fellows exhibit.

The country is full of them. Listen. Dr. Schmoodinary (or some other outlandish name), of *fifty* years' experience, will be at the H— Hotel at such a time, and has never failed to cure (naming a score of chronic diseases) *every* case that he has ever treated. Now, it is perfectly amazing to see the number, and among them quite intelligent people, who will flock to the answer of such an advertisement.

For example, an old clairvoyant woman came to this town some eight or nine months ago, claiming, as they all do, that in a semi-conscious state she could look all through the human body, and was thus able to prescribe just what the sufferer must have to effect a cure.

The fact is, she took out more money during her eight or nine visits here than any honest physician could get in a year. Now, my brethren, these things ought not to be.

We must protect ourselves, and in so doing we will protect the poor and ignorant, who so readily fall a prey to these vultures.

I would like to say something in regard to how the Legislature of the State of Wisconsin have treated the medical profession, if time and space would allow.

Petition after petition has gone in to them, with hundreds of names signed to them, asking them to pass some law to protect our calling, and to say whether men who had not in their possession a legal diploma should be allowed to practise medicine, but all to little or no avail.

If we have no rights that the people are bound to respect, then, in heaven's name, let us do something for ourselves. Will the editor of the GAZETTE please express his opinion on this subject?

Yours respectfully,

F. T. FIELD, M.D.

ELROY, WIS.

#### DERMATITIS VENENATA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—The last two issues of the GAZETTE contain several articles upon dermatitis venenata, its cause and treatment, which have been of much interest to me. One point, however, was overlooked, or may not have occurred to the writers: that is, what appears to be a chronic or periodical form. Vol. x., No. 7, p. 492, article from *Journal of Cutaneous and Venereal Diseases*, the author says, "It has a tendency to a spontaneous cure, and is self-limited." In the majority of cases it does, but now and then a case turns up that, "despite" the treatment, has a way of its own. For instance, a case I have under treatment.

T. P., age 20; clerk. June 8 came to me for treatment. Face, neck, and arms affected. The disease yielded promptly to local application of

R Bismuth, subnit.,  $\mathfrak{z}\text{ii}$ ;  
Sweet cream,  $\mathfrak{z}\text{i}$ . M.

To be applied as often as required to allay burning.

June 26 he again presented himself for treatment. Condition same as before. Ordered same recipe as before. Now during the interval between the two attacks he had not been out of town, nor had he been exposed to the poison that he was aware of. He also informed me that he had been subject to it during the last seven years, that it usually broke out on him during the spring, occurring every three or four weeks, but that

occasionally he would be attacked with it during the fall and winter. He called to see me last January for treatment for the same disease, but I was away at the time, and did not see him again until June 8, as he was only out on a visit to this place at the time. His case may be an exceptional one, or his susceptibility to the poison is so great that the mere contact with any substance that may have been in contact with the rhus will produce it upon him.

Where the bismuth and cream fail to effect a cure, I find the internal administration of a few doses of Fowler's solution and iodide of potassium combined very beneficial. Patients sometimes object to the use of bismuth on account of its turning black after a few hours' exposure to air and light, and the bother of mixing it up every time it has to be applied, but the cooling effect the cream has suffices for the trouble, and the apparent curative effect of the bismuth suffices for its blackness.

R. W. NOBLE, M.D.

BARCLAY, FALLS CO., TEXAS.

### Notes and Queries.

---

#### AN EASY METHOD OF DISTINGUISHING THE SOLUTIONS OF CARBOLIC ACID USED IN SURGERY.

Carbolic acid still maintains a prominent position in the list of antiseptics for general surgical purposes. DR. MATTHEW HAY (*Lancet*, August 7, 1886) gives us a ready method of determining the strength of these solutions. The two strengths of the solution of carbolic acid in common use among those who practise antiseptic surgery are, as every one knows, one of the acid in twenty parts of water (or a five per cent. solution), and one in forty parts (or a two and one-half per cent. solution). These solutions are used for somewhat different purposes, and it is generally of some importance that the one should not be substituted for the other, the more so, as carbolic acid is not a very powerful antiseptic, and moderate dilution of it annuls its action. Now, as labels will drop off occasionally, or even the apothecary may supply by accident the weaker instead of the stronger solution, it may be sometimes desirable to be able to readily distinguish the solutions. The reagent which Dr. Hay proposes for the distinction of the solution is a saturated solution of chloride of sodium. If such a solution is added in about equal quantity to a five per cent. solution of pure crystalline carbolic acid, the

mixture becomes milky and opalescent, and the milkiness does not disappear on shaking ; whereas, if added to a two and one-half per cent. solution, the mixture remains perfectly clear. The opalescence is due to the separation of carbolic acid in the form of minute drops. Chloride of sodium has a greater affinity for water than carbolic acid has, hence it is capable of displacing carbolic acid from its solution. This happens, however, only when the solution of carbolic acid is of sufficient strength. Otherwise they remain side by side in complete solution. In preparing the saline solution, it is preferable to use the pure crystalline sodic chloride employed in laboratories. This is quite a cheap substance. The advantage which this possesses over many of the ordinary varieties of common salt is that it forms a perfectly clear solution on being shaken with water, even though a large amount of undissolved salt be still present, the crystals quickly sinking to the bottom of the vessel in which the solution is being made. On the other hand, a solution of ordinary salt has often a muddy appearance, which only disappears after filtration or long standing. There is no other objection to the use of ordinary salt. The saturated solution can be prepared in quantity and kept at hand as an ordinary reagent, or it can be prepared each time as it is required. A small quantity can be made in less than two minutes, by placing some of the crystals in a test-tube, adding about an equal bulk of water, and shaking vigorously, slightly heating to 40° or 50° C., then cooling under the stream from a water-tap, still shaking, to about 15° C. (60° F.). The heat facilitates the solution without very appreciably increasing the amount of the dissolved salt as compared with that dissolved at the ordinary atmospheric temperature. It is a peculiarity of common salt that its solubility is very slightly raised by heating. It is essential to cool the solution before mixing it with the carbolic solution, for, if it be hot, the carbolic acid will not be precipitated but will remain in solution. It is needless to give directions for the preparation of the salt solution in bulk ; it can be done in the usual way. It is only necessary to keep the bottle containing it in a place where its temperature is not likely in winter to be reduced to very near the freezing-point ; otherwise the strength of the solution may be weakened by the deposition of the salt.

In performing the test, it is advisable to add the carbolic solution to the salt solution,—say in the test-tube,—not the salt solution to the

carbolic solution. If the addition be made slowly, drop by drop, it will be observed that each drop produces a small white cloud of separated carbolic acid, which disappears at once with a single shake of the test-tube until the carbolic solution added is equal to about one-fourth part of the salt solution, when the separated acid no longer disappears on shaking. With every further addition of the carbolic solution the amount of separated acid increases, the fluid meanwhile becoming more and more opaque. The density is greatest when from three-fourths to four-fifths parts of the carbolic solution have been added to one part of the salt solution. With further addition of the solution the acid begins to be redissolved and the milkiness to disappear, and the mixture becomes almost perfectly transparent when about two parts of the solution have been added. If either too little or too much carbolic solution be added to the salt solution, no permanent precipitate of the acid will be obtained. Further, if the temperature of the mixture is above 23° or 24° C. (74° F.), the carbolic acid remains in solution, the solubility of the acid rapidly increasing with the rise of temperature. Should it happen, as it rarely does in this climate, that the temperature of the room is above 24° C., the mixture can be readily cooled by tap-water, or by the evaporation of a few drops of ether or alcohol on the outside of the test-tube in which the mixture is placed. It is necessary, in performing the test, to use test-tubes or glasses which have been previously well dried. A residue of water in the test-tube may prevent the reaction, as will be made evident immediately. It may be well to remark that, on adding a two and one-half per cent. solution of carbolic acid, a slight haziness is sometimes perceptible as a drop falls into the salt solution, but this instantly disappears.

The question now naturally arises, How far can a five per cent. (1 in 20) solution of carbolic acid be diluted before it ceases to give the reaction? It is interesting to find that the addition of quite a small quantity of water is enough to prevent the reaction,—that is, no separation of carbolic acid is obtained which does not disappear on slight shaking. For it always happens that when the stronger solutions of carbolic acid are employed, they give as each drop falls into the saline solution a distinct cloud, but this is at once dissolved on being diffused by shaking through the mass of the mixture. If the strength of the solution be lowered to 4.6 per cent. (1 in 21.7), the reaction is not obtained unless the tem-

perature of the mixture is below  $8^{\circ}$  or  $9^{\circ}$  C. ( $47^{\circ}$  F.); if lowered to 4.5 per cent., the reaction fails unless the temperature is below  $4^{\circ}$  or  $5^{\circ}$  C. ( $40^{\circ}$  F.). A 4.8 per cent. solution gives the reaction quite distinctly, though less so than a five per cent. solution, unless the temperature is beyond  $18^{\circ}$  C. ( $64^{\circ}$  F.). Hence only a solution of greater strength than about 4.8 per cent. (1 in 20.8) can be trusted to give the reaction at the ordinary average temperature of the atmosphere in this country. A solution weaker than 4.5 per cent. (1 in 22.2) will not give the reaction, though the temperature approach zero. It happens frequently that, for convenience, chemists prepare the carbolic solutions from liquid carbolic acid,—that is, acid containing usually about ten per cent. of water; and at least one of the best known makers of the acid states on the label affixed to the bottle that, in dispensing the acid, the water may be disregarded. If chemists follow this instruction, and a five per cent. solution be prepared by *weight*, it will contain only 4.5 per cent. of pure acid, and will therefore not give the above reaction. If it be prepared by *volume*, as is likely in many cases, then, as the specific gravity of the liquid carbolic acid is greater than that of water, being about 1068 (one specimen of Calvert's was found to be 1070), a solution of greater strength is obtained, containing about 4.82 per cent. of acid, and therefore of sufficient concentration to give the reaction. It is thus quite easy to distinguish by means of the reaction carbolic solutions made from liquid and from crystalline carbolic acid, if both have been made by weight.

If it is desired to render the sodic chloride solution more sensitive, it can be readily done by saturating it with carbolic acid. Dr. Hay finds that a saturated solution of the chloride at  $15^{\circ}$  C. is still capable of dissolving carbolic acid to the extent of about 0.95 per cent., or, roughly, one per cent. Such a solution is best prepared by dissolving the salt to saturation in a one per cent. solution of carbolic acid. When the solution has become fully saturated, it will have a hazy appearance, from the separation of a little carbolic acid; this can be readily removed by filtration. If this solution be used instead of the simple salt solution, then it will be found to precipitate the carbolic acid more freely than the other, and, in the case of solutions stronger than 4.5 per cent., at any temperature under  $32^{\circ}$  to  $35^{\circ}$  C. ( $93^{\circ}$  F.); but this increase in the sensitiveness of the reagent is gained at the expense of diminishing its value for the purpose of dis-

tinguishing carbolic solutions slightly weaker than five per cent. from those which are stronger. The reagent is now capable of precipitating carbolic acid in any solution stronger than three and one-half per cent. In solutions weaker than three per cent.—therefore in a two and one-half per cent. (1 in 40) solution—no precipitate is formed, or, if it is, it at once disappears on shaking. If the surgeon wishes merely to possess a reagent which will readily, and at any ordinary atmospheric temperature, enable him to distinguish a five per cent. from a two and one-half per cent. solution of carbolic acid, the carbolized salt solution is decidedly preferable to the simple salt solution.

There is still another way in which chloride of sodium may be employed,—viz., for the distinguishing of very strong and very weak solutions of carbolic acid,—not the usual surgical solutions. It depends on the fact, which Dr. Hay has ascertained, that while a perfectly saturated solution of the salt is still capable of dissolving about one per cent. of carbolic acid without separation or displacement of the salt, yet a perfectly saturated solution of carbolic acid cannot dissolve more than the fragment of a crystal of the salt without the acid beginning to separate. Hence, if, on dissolving a small crystal or two of common salt in a solution of carbolic acid, the fluid becomes opalescent, and the opalescence does not appear on shaking, the solution is a saturated one,—that is, it contains about seven and one-half per cent. of acid. If, on the other hand, no opalescence appears, not even when so much salt has been dissolved in the carbolic solution, by shaking and slight heating and subsequent cooling, as that the solution has become saturated with the salt, then the original solution contains less than one per cent. of acid.

It is perhaps desirable, in conclusion, to briefly summarize the contents of this communication. The three reagents suggested are: 1. A saturated solution of chloride of sodium. This precipitates carbolic acid from solutions stronger than 4.8 to five per cent., at a temperature not exceeding  $18^{\circ}$  to  $24^{\circ}$  C. ( $64^{\circ}$  to  $75^{\circ}$  F.). It causes no permanent precipitate in weaker solutions. 2. A carbolized saturated solution of carbolic acid. This precipitates carbolic acid from solutions stronger than three and one-half per cent., and it does so, in the case of solutions above four and one-half per cent., at any temperature below  $32^{\circ}$  to  $35^{\circ}$  C. ( $90^{\circ}$  to  $95^{\circ}$  F.). It gives no permanent precipitate with weaker solutions.

This is the best reagent for the simple distinction of the usual surgical solutions,—two and one-half and five per cent. 3. Solid chloride of sodium. A small crystal of this precipitates carbolic acid from a saturated solution; whereas, when dissolved even to saturation in a weaker carbolic solution than one per cent., it gives no precipitate.

#### CONSTITUENTS OF LOBELIA.

*Lobelia nicotianæfolia* is indigenous to Southern and Western India; the infusion of the leaves is used as an antispasmodic. The lower part of the stem is woody, about one and a half inches in diameter; the upper part is hollow and tubular. The leaves resemble tobacco-leaves in shape, are finely toothed and hairy. The capsules are of the size of a pea, two-celled, and contain numerous light brown seeds which are about one-fiftieth of an inch long, oval, flattened, and finely striate. The dried plant is covered with numerous resinous dots, and has an acrid, biting taste. DR. H. v. ROSEN (*Amer. Journ. of Pharm.*, August, 1886) obtained from the powdered herb—

Moisture.....	12.77
Ash (of which 2.04 per cent. was soluble in water).....	9.35
Sand.....	0.47
Albuminoids and alkaloids soluble in water....	2.49
Albuminoids soluble in soda solution.....	8.23
Insoluble albuminoids.....	9.09
Cellulose.....	28.58
Fat and other substances soluble in petroleum benzin.....	3.68
Resin and chlorophyll soluble in ether.....	2.01
Mucilage soluble in water.....	2.50
Metarabic acid (pectin).....	0.27
Lobelic (?) and other vegetable acids.....	6.21
Amylaceous substances.....	1.29
Other substances soluble in water.....	1.60
Other insoluble bodies (cuticular substances, lignin, etc.).....	11.46
	100.00

The presence of alkaloids was ascertained from the acid infusion which was successively agitated with petroleum benzin, benzol, and chloroform, then rendered alkaline with ammonia and agitated as before. The benzin solution from the alkaline liquid contained the liquid alkaloid *lobeline*, and the chloroform solution when evaporated left striated prisms of another alkaloid; minute quantities of the latter were also found in the benzol solutions from both the alkaline and acid liquid, and a somewhat larger quantity in the chloroform solution from the acid liquid. The benzin solution of *lobeline* gives with ether and

hydrochloric acid a whitish precipitate of *lobeline hydrochlorate*, and this salt yields with Frøehde's reagent the characteristic red color passing into violet, and gives precipitates with picric acid, auric chloride, and with bromine in potassium bromide. The second alkaloid yields heavy precipitates with the usual reagents, except picric acid and tannin, which cause in the solutions a slight turbidity; Frøehde's reagent gives a brown color changing to green, and sulphovanadic acid causes a cherry-red or violet-red coloration.

The same two alkaloids were also obtained from *Lobelia inflata*, *Lin.*, though the volatile *lobeline* was present only in minute quantity, the herb having been on hand for a prolonged time.

The physiological experiments were made with *lobeline sulphate* prepared by Merck, and with the two alkaloids obtained from the above species obtained by Dr. Ott, though the author's explanation differed somewhat from Dr. Ott's.

#### LOSS OF WEIGHT IN EPILEPSY.

DR. F. HALLAGER, assistant physician to the lunatic asylum at Viborg, has endeavored to find an explanation of the diminution of the weight of the body after an epileptic attack. Kowalewsky was the first to draw attention to this fact. He states "that all persons suffering from any form of epilepsy lose in weight after each attack." "This occurrence is not equally great in every case, but depends on the duration of the disease and the intensity of the attack. The loss of weight is greatest after the first attack of a series of epileptic fits." Dr. Hallager has drawn up a table indicating the weight of the body and the quantity of urine and fæces excreted by the patients each day during his researches. Solid or liquid nourishment was given to the patients in proportion to the frequency and violence of the attacks. By a chart accompanying the paper in the *Nordisk. Med. Arkiv* it appears that whenever the curve of weight is considerably depressed after an attack there is also a corresponding elevation in the urine curve, of which no explanation is afforded by any increase of diet. When a loss of several pounds takes place, it is owing to the secretion of an abnormal quantity of urine. Dr. Hallager has been unable to determine whether the production of urea is also increased by the attack, but he believes the increased formation of urea is not sufficiently great to be of importance in the loss of weight. The dimi-

nution of weight caused by an epileptic attack he considers to be due to an increased secretion of urine after the fit. M. Kowalewsky insisted that psychic epilepsy, as well as the *grand* and *petit mal*, is followed by a diminution of weight. This is contrary to Dr. Hallager's opinion, who believes that there is no diminution during this psychic state except when the patient refuses all nourishment, and that the quantity of urine secreted is much less than normal. This is no doubt due to a reaction after the preceding augmentation. The fact that psychic troubles of an epileptic origin (especially when of long duration) may, like other maladies, cause a loss of weight, is natural; but this loss, which arises from general emaciation, has nothing in common with the diminution of weight after an epileptic attack, which results from a diminution of the quantity of water in the body, due to preceding augmentation of urine.—*Lancet*, August 21, 1886.

#### UNTOWARD EFFECTS OF PARALDEHYDE.

In 1884, acting on the suggestion of Dr. Keraval, DR. JAS. G. KIERNAN tried paraldehyde as a means of securing slumber in excited cases. It was generally stated that paraldehyde had all the good qualities of chloral hydrate, without its bad effects. At first sight such a statement was improbable, because the evil and good effects of chloral hydrate arise from its physiological action, and any remedy having the good effects of chloral hydrate must have the bad effects in a minor degree.

He found, after very careful experimentation, that paraldehyde produced irritation of nearly every mucous membrane in the body as a secondary consequence of its soporific effect; that it markedly impaired digestion; that scarlatina form skin eruptions, attended by itching and scaling off of the skin, frequently followed its use. Irritation of the eyes was as frequent as after the use of chloral hydrate. The same intractable nail ulcers followed its brief use, as so frequently follow the long-continued use of chloral hydrate. Paraldehyde, in his hands, has shown all of the untoward results of chloral hydrate, while the slumber produced by it has been neither so profound nor so refreshing as that produced by the latter. None of these results were due to methods of administration or impurities of the drug. In his opinion it hardly comes up to the requirements of a hypnotic.—*Western Druggist*, September, 1886.

#### BACTERIUM TERMO TREATMENT.

DR. ROQUER Y CASADESUS, of Barcelona, having a case of laryngeal and pulmonary phthisis of an advanced character, and wishing to test the value of Cantani's bacteriotherapeutics, asked Dr. Rodriguez Mendez, a well-known microbiologist, to assist him. The condition of the patient was carefully ascertained in consultation, cavities being found in both apices. There was a high temperature, also profuse sweats, diarrhoea, profuse expectoration, great dyspnoea; in fact, every sign of acute pulmonary tuberculous degeneration. The patient was in the seventh month of pregnancy. A pure culture of bacterium termo was then prepared by Dr. Botey, and made use of both by means of inhalations twice a day and by intra-laryngeal applications. After a few days the patient's condition was improved, the temperature having fallen from 39° to 38° or 38.4° C. This improvement continued till labor came on, which was of a normal character, but shortly after delivery the woman's condition became alarming, and she died in twenty hours. Dr. Roquer concludes from this case that, whether the remission of temperature was or was not due to the treatment, the bacterium termo was perfectly innocuous, as Professor Cantani states it to be. Dr. Philipovich, who has made several trials of the treatment of phthisis by the inhalation of cultures of bacterium termo, has published a paper describing the results obtained in the reports of the Odessa Medical Society. In one case the inhalations had to be stopped in consequence of the condition of the patient becoming worse, three cases died, and two were discharged. Dr. Philipovich's observations agree in general with those of Dr. Görbersdorf, and are decidedly inconsistent with those of Professor Cantani. The expectoration did not diminish, but it was rather more easily secreted, and so the dyspnoea was less. This, however, was probably due to the action of the water and the better aeration of the lungs rather than to the microbe. In one case the quantity of sputum was increased, and it became more liquid and very offensive. At the necropsy in this case cavities were found containing tolerably pure cultures of bacterium termo. In none of the cases did the tubercle-bacilli in the sputum disappear or even diminish, though the inhalations were continued for seven weeks. Again, no effect was produced on the temperature or sweats, and in all the patients there was noted a greater or less loss of weight. The author concludes that no beneficial effect can be

looked for from the use of this method of treatment; indeed, it would rather appear, from the post-mortem appearances above mentioned, that inhalations of bacterium termo may be positively hurtful to the human organism.—*Lancet*, August 21, 1886.

#### SACCHARIN.

The conclusions arrived at by Stutzer concerning the innocuousness of saccharin when taken into the human body have recently been confirmed by PROF. SALKOWSKI (*Virchow's Archiv*, cv. p. 46); and PROF. DRESCHFELD, of Owens College, Manchester, has ascertained that when given in diabetes it does not affect either the quantity or the sugar passed. It has scarcely any retarding effect on the digestion of either proteids or carbohydrates, and in two cases of acid dyspepsia it was found to relieve some of the troublesome symptoms. It has also been found that added in small quantities it increases the diastatic action of malt in the presence of sugar.—*Pharm. Journ. and Trans.*, August 28, 1886.

#### TESTS FOR THE PURITY OF MILK.

What process affords the simplest and most accurate tests for determining the quality of milk, was the subject of a paper read before the Massachusetts Pharmaceutical Association by W. W. BARTLETT (*Western Druggist*, September, 1886), who called attention to the various procedures used by adulterators of milk, and discussed various methods of discovering the same, giving preference to Wanklyn's method. Milk should have a specific gravity at 60° F. of 1029 to 1033; if fresh, should have a slight acid reaction; alkaline reaction in alleged fresh milk indicates adulterants; excessive acid reaction indicates lactic fermentation. The cream should be determined by a 100 c.c. tube, graduated into cubic centimetres, and the volume read off at the end of twenty-four hours. The total solids are then determined as follows: If a porcelain capsule be used to evaporate the milk, a small amount of pure white sand should be added to the latter, after having been washed, heated red, cooled, and then weighed with the capsule (the sand breaks the film formed on the drying milk). It is best, however, to use a perfectly flat-bottomed platina capsule, two and one-quarter inches in diameter and one-half inch deep. The capsule, being perfectly

balanced on the scales, five grammes of milk are carefully weighed into it. The dish is then placed on a water-bath, heated till apparently dry (takes about one to one and one-half hours). It is then placed in a hot-air oven, and exposed to a heat of 220° F. for half an hour, by which time its weight will be constant. The difference between the weight of the empty capsule and its present weight will be the weight of the solid constituents of the milk. The capsule and contents are next placed upon a water-bath, and boiled with three successive portions of petroleum benzine, decanting off each portion carefully after boiling for a minute. The capsule is then carefully washed off with benzine, dried in the oven, cooled in a desiccator, and quickly weighed; as the fat is removed by this process, the difference between this last weight and the former is the weight of the fat. The other solids ignited at a red heat yield the percentage of inorganic salts. The amount of water present is easily determined. Thirteen per cent. of water found in each sample in excess of eighty-seven per cent. allowed by law, represents one per cent. of added water. The amount of milk-sugar may be determined by a standard Fehling's solution, or the polariscope; the last yields the best results.

#### TRIBROMIDE OF ALLYL.

Tribromide of allyl is another compound that has only had its possible use in medicine discovered after a period of years. It was first prepared by Wurtz in 1857 (*Ann. de Chimie*, li. 91) by the reaction of iodide of allyl on one and a half times its weight of bromine, and is a colorless liquid, soluble in ether, boiling at 217° C., and having a specific gravity of 2.436. According to DR. DE FLEURY (*Archives de Pharm.*, August, page 352), this compound has been employed with good effects in hysteria, asthma, angina pectoris, and infantile convulsions. It was administered in capsules, each containing 5 drops, two to four capsules being given daily, or subcutaneously in doses of 2 to 4 drops dissolved in one or two cubic centimetres of ether.—*Pharm. Journ. and Trans.*, August 28, 1886.

DR. SCHMITZ, of Bonn, reports in the *Centralbl. f. Kl. Med.* vii., 15, 1886, two cases in which the vapor of carbolic acid (employed in pneumonic catarrh and diphtheria) caused clonic-tonic convulsions.

### ON THE BEVERAGES IN COMMON USE.\*

BY PROFESSOR DUJARDIN-BEAUMETZ.†

**G**ENTLEMEN:—In the previous lectures I have spoken of complete and complex aliments; it remains for me to consider the drinks in ordinary usage, and this will be the subject of this day's lecture. For convenience I shall treat of beverages under three heads,—

\* A lecture on Hygienic Therapeutics. Translated from advance sheets.

† Member of the Academy of Medicine, Physician to the Cochin Hospital, Paris, France.

water, aromatic beverages, and alcoholic beverages.

Water plays an indispensable part in the alimentation of man, constituting more than two-thirds (seventy per cent.) of the bulk of the organism. It cannot, then, be omitted from the daily rations of man, and, if we include in our estimate the aqueous principles contained in foods, a man ought to consume three thousand grammes (or somewhat more than three quarts) of water a day.

I cannot here do more than touch upon this question, which is so important from a hygienic point of view, and if I were to attempt to treat the subject of drinking-waters with any proper degree of fulness I should require several lectures. Therefore I can only call

your attention to a few points of interest which have especial reference to hygienic therapeutics, then I shall briefly consider water in reference to certain general properties, and I shall lastly allude to the mineral waters (called table-waters), natural and artificial.

Water contains air and salts. The presence of air is absolutely necessary to render water potable. Boussingault insists that such water should contain at least from twenty-five to fifty cubic centimetres of gases per litre. These gases should consist of from eight to ten per cent. of carbonic acid, and of a mixture of oxygen and nitrogen containing from thirty to thirty-seven per cent. of oxygen and sixty-three to seventy per cent. of nitrogen.

When water is deprived of these gases it becomes "flat" and indigestible, as is the case with boiled water and the water that melts from the glaciers. Boiled water must first be aerated by churning before it is fit to drink, and glacier water becomes aerated naturally as it forms cascades in its course.

Are the salts also as useful as air in rendering water potable, and is drinkable water fairly represented by water which is chemically pure, corresponding exactly to the formula  $H_2O$ ?

In France, since the experiments of Dupasquier, and those especially of Boussingault, the opinion prevails that the mineral ingredients, carbonates, sulphates, etc., must attain at least the figure of fifty centigrammes per litre in order that water may be fit for drinking purposes. These salts are absolutely necessary for the constitution of the skeleton, especially in the early life of man and animals. In England this view is not entertained, and Frankland has given expression to the opinion that as man finds in his food the quantity of lime necessary for his nutrition, the water which he drinks is the purer and better the more it resembles distilled and thoroughly aerated water. However this may be, when the proportion of calcareous salts is too high, the water becomes hard, and is liable to cause constipation.

Therapeutics has utilized the properties of these limy waters in the treatment of diarrhoea, persons suffering from this affection being often benefited by drinking the hard water of certain wells; and lime-water, which is the familiar combination of water and slaked lime, renders us great services in diarrhoeas (especially in infantile therapeutics); the constipating properties of milk are augmented by the addition of lime-water.

Water contains a great number of micro-organisms, the study of which has so recently been made, and the schizomycetes of various waters have been analyzed. In this interesting line of study Marié Davy and Miquel, at the Observatory of Montsouris, have made valuable contributions. Taken in their aggregate, these micro-organisms may be divided into three groups. Those of the first are favorable to the health of those using the waters, those of the second are indifferent, those of the third injurious.

The first assimilate the carbon and eliminate the oxygen of carbon-dioxide; they aerate the water. This is the office of certain algæ containing chlorophyll, and especially the rôle of diatoms. The baneful micro-organisms consist of the microphytes of putrefaction. They set free nitrogen under the form of ammonia, and render the water putrid and injurious.

The waters of drinking sources may also contain the micro-organisms of infectious diseases, among which the bacteria of cholera and typhoid fever claim especial mention. Lastly, the ova of various entozoa may also infect sources of water-supply, and it is, as you know, through the contamination of water with the dejections of dogs infested with the *Tænia echinococcus* that man, drinking this water, becomes the victim of hydatid cysts.

Leaving one side the "infinitely little," one may, as Gérardin has shown, judge of the quality of any kind of water by its flora and fauna. As for the flora, if the water-cress (*Nasturtium officinale*) is not, as it is held to be in popular estimation, the health of the body, it is the health of the streams. Wherever it grows the water is wholesome, while, on the contrary, the duck-weed, or water-lentil (*Lemna minor*), always indicates a water of bad quality. As for the fauna, it is everywhere known that the water of streams which are deprived of fishes and mollusks is unfit for drinking purposes.

The temperature of water destined to be drunk is a matter of some importance. Water when iced stimulates the digestive functions when taken in small quantity, and lowers the temperature. Liebermeister estimates this depression of temperature at  $0.45^{\circ} C.$ , and Winternitz at  $0.22^{\circ} C.$  for the axilla. The usage of ice-water, however, when prolonged, leads to diarrhoea and intestinal irritation, and doubtless much of the gastro-intestinal disorder of countries where free use is made of ice-water is due to this cause.

As for the refrigerant action in general of

cold water, if it may be the determining cause of pulmonary and other congestions, as has been observed as a sequel to lavage of the stomach with too cold water, it may, nevertheless, be utilized as a powerful antithermic means in the febrile process: in fact, in pneumonia and typhoid fever we derive a real advantage from the use of cold drinks.

Warm water, on the other hand, determines a rise in the temperature of the body, and it may be affirmed that all our sudorific herb teas, with the exception of such as may contain *jaborandi* and its alkaloid *pilocarpine*, which act directly on the sweat-glands, owe their property not to the medicinal principles which they contain, but to their temperature. These hot draughts render us great service, as is known, in the initial periods of eruptive fevers, but they are likely to disturb digestion and provoke vomiting, and they do not quench thirst.

All parts of the digestive tube may absorb water. This is so true of the buccal mucous membrane, that liquor-tasters—a class of professionals whose business it is to test the quality of liquors by holding a mouthful, mingled with air, in their mouth, and then spitting it out—have been known to experience more or less intoxication from the simple testing of liquor in this way, and many a liquor-taster has become a drunkard. It is, however, in the intestine that the absorption of liquids principally takes place. *Béclard* has shown that water passes very rapidly into the intestinal canal. He has found it two minutes after being swallowed in the duodenum of a man the subject of a duodenal fistula, and, six minutes after being swallowed, in the *cæcum* of a horse.

I have in my hospital service instituted another series of experiments, showing with what rapidity water disappears from the stomach. In a patient affected with a slight degree of dilatation of the stomach, after having well emptied the gastric cavity by means of a stomach-pump, I introduced a quart of water. At the end of an hour there remained but a half-pint in the stomach. On frequently repeating this experiment, I have found that, on an average, a quart of water per hour will pass from the stomach into the intestine.

The water after being absorbed is rapidly eliminated by the kidneys; it never accumulates in the blood, and determines no alteration of the *hæmoglobin*. *Leichtenstern*, in an individual who had drank seven quarts of water, found no modification in the composi-

tion of the blood. This rapid absorption, and no less rapid elimination of water by the urine, sufficiently explain the diuretic effects of water, and my regretted master, *Bouchardat*, was right in saying that water is the best and most powerful diuretic.

The greater part of our mineral waters, called diuretic waters, such as *Contrexville*, *Evian*, *Vittel*, etc., are only such by virtue of being well tolerated by the stomach, and their ready absorption and elimination. This diuretic action of water is of exceeding importance, and the numerous applications thereof will be apparent in the course of these lectures. As for the action of water on nutrition, I shall not refer to this again. Already, in a previous lecture on the primordial alimentary principles, I showed you that experimenters have arrived at different conclusions, one party maintaining with *Genth*, *Bischoff*, *Forster*, *Henneberg*, *Stohmann*, *Schmiedeburg*, *Germain-Sée*, *Albert Robin*, that water augments the excretion of urea, and may be considered as an agent of disassimilation; the other party, basing itself on the very accurate experiments of *Débove* and *Flamant*, claiming that water has no influence on the excretion of urea, nor can it be said that the question is yet definitely settled. I come now to the subject of the table mineral waters.

In the volcanic region of Central France (*Auvergne*) we find a great number of springs charged with carbonic acid. These waters, which do not differ in their composition save in the quantity of carbonic acid which they contain, constitute our principal table mineral waters; chief among them are *St. Galmier*, *Condillac*, *Chabetout*, *Morny-Châteauneuf*, and *De l'Ours*. These table-waters are pleasant to take and of great purity. By the carbonic acid which they contain they quiet the stomach and regulate digestion. Their purity makes them especially sought after in times of epidemic. At the same time it will not do to use them exclusively, for they get the stomach accustomed to their stimulation so that it will not digest food without the help of its gaseous draught, and they eventually exhaust the stomach. Lastly, do not forget that certain patients are absolutely rebellious to the administration of these effervescent waters, which may provoke in such persons irritations of the digestive tube.

In connection with these natural mineral waters, I shall say something about the artificial seltzer waters, manufactured now on so large a scale. They are in reality not nearly so good as the natural, and by reason of the

low price of the latter, there is but little justification for the substitution.

Moreover, the closeness of union between the carbonic acid and the water which exists in the water as it flows from the springs cannot be imitated in any artificial combination. When the manufactured seltzer water is drunk the gas escapes with too much force and volume, and may oppress the stomach; besides, the gas with which the water is charged may contain impurities from faults in its fabrication. Moreover, the presence of the carbonic acid in the water is no guarantee of the purity of the latter, whose source may not have been free from pollution. Lastly, according to Armaud Gautier, the metallic armatures of the siphons contain lead, and this metal is almost always found in the artificial seltzer waters.

I have finished what I had to say regarding water, and I come now to our second division, which comprises the aromatic beverages.

Under the head of aromatic beverages I propose to speak exclusively of such as contain a certain alkaloid, with the formula  $C_8H_{10}N_4O_2$ , which Runge, in 1820, found in coffee, and to which he gave the name *caffeine*, which Oudry, in 1827, found in tea, and which he called *theine*, which Martins discovered in the Paullinia sorbilis, and which finally Hæckel and Schlagdenhauffen have isolated, along with theobromine, in kola nuts.

In order to simplify the exposition into which I am about to enter, I will admit that all these alkaloids are identical, although I know very well that it is by no means demonstrable that isomeric bodies have absolutely the same physiological action. I shall not touch upon the different hypotheses which have been put forth relative to the atomic composition of this body. I have already called attention to this point in a recent study on the derivatives of caffeine.\* I have shown that if, according to Strecker, caffeine is only the methyltheobromine, according to Fischer, on the contrary, caffeine and theobromine are derivatives of xanthine; theobromine is the bimethylxanthine, while caffeine is the trimethylxanthine. But I cannot now take up your time with these chemical researches.

All the aromatic beverages containing caffeine (or the isomeric alkaloids above mentioned) for their bases are used in immense quantities all over our globe, and their em-

ployment is much more extensive than that of alcoholic beverages.

Many opinions have been put forth as to the physiological and hygienic action of coffee. These may be reduced to three hypotheses. Coffee diminishes the excretion of urea and is a waste-restrainer; it does not modify the urea excretion, and is a force-producer; or, lastly, it acts as a food, supplying elements of nutrition.

The first view is supported by Schultz, Gasparin, Boker, Lehman, Frœlich, Trouseau and Pidoux, Rabuteau, Marvaux, etc., who claim that coffee diminishes the quantity of urea excreted; that it does not nourish, but that it prevents denutrition. This is the waste-restraining-aliment theory.

But to facts advanced by these physiologists other facts are opposed, and we see Roux and Giraud in France, Binz in Germany, Brackenridge in England maintain that coffee, as well as caffeine, in no respect modifies the figure of urea. Hence Gubler, basing himself on the researches of these authorities, affirms that coffee has no action on nutrition, but that it is a tonic, or, rather, a force-producer.

Lastly, Payen has shown that coffee contains nitrogen, and this in quite notable proportion, since in green coffee this essential element exists in the proportion of 4.48 per cent., and in roasted coffee in the proportion of 1.75 per cent. He shows, moreover, that the admixture of coffee with milk, in ordinary usage in many parts of the world as a breakfast beverage, is one of the most nutritious of all drinks, a mixture of 500 gms. of infusion of coffee, 500 gms. of milk, and 75 gms. of sugar containing, according to his estimate, 49 gms. of nitrogenous substance and 100 gms. of hydrocarbon and salts.

This view has been adopted by Fleury, Bouchardat, and Jomand, and is supported by facts, being in accordance with the experience of entire populations (in England, Germany, Switzerland, and the United States), who find sustenance in their breakfast dish of coffee.

Coffee is, then, by virtue of the nitrogen which it contains, a food, and you remember that in the primordial alimentary principles I included caffeine among the azotized substances. Moreover, recent experiments of Guimaraës show positively that augmentation of urea follows the administration of coffee.†

\* Dujardin-Beaumetz, "On the Physiological and Therapeutic Properties of the Derivatives of Caffeine" (*Bull. de Thér.*, 1886, t. cx. p. 241).

† Guimaraës, "On the Physiological and Hygienic Action of Coffee" (*Arch. de Phys.*, 1884, t. iv. p. 253).

But is coffee anything but an aliment? It possesses special tonic properties on the circulation and nervous system. All experimenters are agreed in the fact that under the influence of coffee the beatings of the heart become more rapid and more energetic, the circulation more active, and the urine more abundant. Leblond's study has given us in this regard tracings of high importance. Moreover, whether by the activity which it impresses on the circulation, or by a direct action on the nervous elements, coffee directly affects the brain, and may be called "a cheering and thought-inspiring beverage."

This threefold action, on nutrition, on the circulation, and on the nervous system, makes coffee an admirable tonic, and we are justified in saying that it is largely by reason of the strong coffee, which habitually forms a part of their diet, that our troops have been enabled in the burning climate of Algiers to endure the most exhausting campaigns.

It is also owing largely to the coffee, which is becoming more and more an article of daily consumption among the farmers in the country, that we see this class of people able to endure the great increase of toil to which they are subjected in haying and harvesting seasons.

Coffee, in order to be fit for nutrition, must first be torrefied. Payen has made a special study on the modifications which coffee undergoes by roasting, and has shown that during this process there is a breaking up of the chlorogenate of potassium and caffeine, and a setting free of a part of the caffeine held in combination.

I cannot here touch upon the different modes of preparing coffee, modes by which the properties of roasted coffee are doubtless more or less modified. While in Europe it is the infusion which is drunk almost exclusively, the inhabitants of the East prefer the decoction, and, if we may believe their statement, the decoction, while preserving the tonic and alimentary properties of the coffee, is quite devoid of the exciting properties which characterize the infusion.

The different physiological properties of coffee have caused this food medicine, and its congeners, tea, Paraguayan maté, guarana, and kola, to be applied to the treatment of a great number of affections. Its tonic action on the circulation has led to its use in the treatment of diseases of the heart, and Gubler, Lépine, and Huchard have shown us all the advantages derivable therefrom. Its di-

uretic properties have led to its being recommended in dropsies, urinary gravel, and gout. Its cerebral tonic action has rendered it useful in the treatment of migraine and cephalalgia. Lastly, we see its utility recognized in intestinal strangulations and opium-poisoning.

I have finished what I wished to say concerning coffee, leaving aside what appertains to infusions made from roasted acorns and chiccory, which contain nitrogen, and probably have some food value, but are devoid of caffeine, and therefore of the tonic and excitant properties of coffee.

It remains for me to speak of alcoholic beverages. This is a topic of special interest and importance, and you will permit me to dwell on it at some length. We will study successively alcoholic beverages in general, then the physiological action and digestibility of these beverages. As for alcoholic beverages in general, I shall divide them into three classes: the first includes wine; the second, cider, perry, and beer; the third, distilled spirits and aromatized liquors.

*Wine.*—It is a profound mistake to suppose that wine is only a mixture of water and alcohol. It is a complete *living whole*, if I may so express myself, all the elements of which constitute so complex and homogeneous an aggregate that we cannot alter any one of them without introducing profound modifications into the composition of the wine. Apart from the water and the alcohol, wines contain glycerin, tannin, essential oils, ethers, salts, and, in particular, tartrates; and, according to the period when you examine the wine, the quantity of these different elements varies.

Wine is, in fact, as I just told you, a living thing, by the fermentations which it undergoes. It has its youth, its maturity, and its old age. Such crude wines as those of Burgundy are short lived, and their old age is early. Other crude wines, like those of Bordeaux, have a much longer life, and to hasten their maturity are even sent to distant places. Lastly, wines have their diseases, which generally result from want of skill in their fabrication, and from a vicious fermentation determined by the presence of impure products.

The following table from Chevalier and Bandrimont gives the percentage of alcohol in different wines:

Wine of Marsala.....	23.83
" " Red Madeira.....	20.52

Wine of White Madeira.....	20.00
“ “ Port.....	20.00
“ “ Bagnols.....	17.00

By glancing over this table you can judge how variable are wines in respect to their richness in alcohol. From a fiscal point of view, all wines having more than twenty-five per cent. of alcohol are considered as liquors, and all that are above 15.90 per cent. pay double duties. This limit ought to be made even lower, and no wines that contain more than ten or twelve per cent. of alcohol should be allowed to pass for wines of ordinary consumption. Bear in mind, in fact, that our table wines, and our most celebrated raw wines,—the Château-Lafitte, the Château-Margaux,—do not contain more than 8.75 to 8.88 per cent. of alcohol, and that our wines of Central France scarcely have seven per cent.

If I insist so much on this point, it is because vehement debates have been aroused in our legislative assemblies and in the Academy of Medicine concerning vinage, or the alcoholic adulteration of wines. I am a thorough opponent of the right of vinage, which, by introducing into wines foreign spirits, modifies and profoundly changes the wine; in fact, in my estimation, spoils it. By the commercial treaties which bind us to Spain, and which allow the introduction of wines with sixteen per cent. of alcohol, we see all the spirits of bad quality fabricated in Germany enter our country under the cover of wine.

These wines thus alcoholized entail deplor-

able consequences on public hygiene, and they have substituted for the drunkenness resulting from the abuse of wine all the worst evils of intemperance seen in other countries where alcoholic stimulants of bad quality are in common use, and we see the fruit of this abundant consumption of strong wines in the grave disorders of the nervous system and the other tissue-degenerating diseases now so prevalent.

But the limits of this lecture will not allow me to dwell further on the alcoholization of wines, which is a subject of the greatest importance.

From a medical point of view, wines may be considered under four heads,—the strong wines, the red wines, the white wines, and the sparkling wines.

The strong wines are those which contain fifteen per cent. or more of alcohol. These are generally dry wines, which, by their great richness in alcohol, are indicated in febrile maladies and states of prostration where stimulants are required. Unquestionably, the wines of Marseilles, of Madeira, of Malaga, also sherry and port, are superior to Todd's potion, which is ordinarily prescribed in our hospitals.

The red wines, by the tannin which they contain, are the tonic wines *par excellence*. Their intoxicating power is not necessarily in relation with the alcohol which they contain, but rather with the ethereal principles which enter into their composition; and I need only remind you here of the distinction, so well recognized, between the Burgundy and the Bordeaux. The first, by the heady “bouquets” which distinguish them, excite the brain much more than the Bordeaux wines; hence it is that the latter are the most often prescribed in sickness.

The white wines, which contain much less tannin than the preceding, because, being made from the black grape, they owe their white color to the fact that they were not kept in prolonged contact with the skins and pulp of the grape, contain, on the other hand, more of the potassic tartrate. They are the diuretic wines *par excellence*, and even Hippocrates noted their action on the kidneys. Certain of these white wines which are a little tart, when diluted with our alkaline waters, constitute an agreeable beverage and possess undisputed diuretic properties.

As for the effervescent wines, of which the type is champagne, they render us important service in medicine. By the carbonic acid they contain, and which is intimately com-

bined with them, they have a marked calmative action on the mucous membrane of the stomach; hence whenever, in cases of irritation of that viscus with vomiting (as in peritonitis), there is indication for an alcoholic stimulant, these sparkling wines serve a good purpose. Here we often find nothing better than iced champagne, whose effects not seldom are marvellous.

The second class of alcohols consists of the fermented beverages,—cider, perry, and beer; the two former, which are the product of the fermentation of apples and pears, are widely in use in France. Girard, the director of the municipal laboratory of Paris, who has made a careful analysis of cider, has shown that an ordinary sample of this fermented beverage contains five to six per cent. of alcohol, about three per cent. of ash, and watery extract in the proportion of about one ounce per quart. As for the sweet ciders, they contain a much smaller quantity of alcohol, which does not exceed 1.70 per cent.

Apart from the alcohol which enters into its composition, cider contains a large quantity of alkaline salts, phosphates, carbonates, malates, etc.; hence it is that cider is diuretic, and Denis Dumont has highly extolled the usage of this beverage in the treatment of gout and the uric acid diathesis. The considerable proportion of potassic salts which it contains also renders it slightly purgative; and hence it is that cider is much resorted to by some persons for a laxative effect.

Compared with cider and perry, beer, ale, and porter are of much more general usage, and it may be affirmed that in Europe there are more beer-drinkers than wine-drinkers.

Beer, as you know, results from the fermentation of the starch contained in certain grains. During germination the starch of the grain is transformed by the vegetable diastase into grape-sugar, and this natural process is utilized in the fabrication of beer by the fermentation or maltage of barley. To this sweet infusion of malt or wort is added infusion of hops, which communicates its special taste, and the fermentation is effected either under heat or cold.

We find in the fermentation of beer a demonstration of the laws established by Pasteur, that each of these fermentations has its special organic conditions, the high yeast corresponding to the fermentation which takes place at from 15° to 20° C., and the low yeast corresponding to that which takes place at 4° or 5° C. Lastly, an impure kind of malt

yeast—the *saccharomyces Pastorianus* of Ress—produces a bad fermentation of the beer.

These beers, if we may trust Girard's analysis, which I place before you, contain a proportion of alcohol varying from three to seven per cent. The strongest beers, as you well know, are the English.

Beers which contain less than three per cent. of alcohol are called small beers, or beers of consumption, and must be drank as soon as made or they will spoil.

These malt liquors are very diuretic, and this property is largely proportioned to the quantity imbibed. The beer-drinker is not easily satisfied, for beer is a beverage that is not good to quench thirst. The more one drinks of beer the more he wants to drink, and it suffices to go through the breweries of certain countries, as those of Munich, to see what enormous quantities a man can drink. Some have been known to exceed twenty quarts a day. Fortunately, however, owing to the diuresis which it excites, a quantity so excessive does little but pass through the economy, transforming the beer-drinker into a veritable filter. This continued stimulation of the kidneys, however, is not unattended with serious evils, and we see renal degenerations follow the forced labor to which these glands are subjected.

By the diastase which they contain these malt beers supply a nutrient which has a digestive action on the carbo-hydrate aliment-

any principles; hence vegetarians ought to be beer-drinkers. Certain liquid malt preparations in the markets (Hoff's, Wyeth's, Nicholson's, etc.) are beers rich in diastase and dextrine. Lastly, there are medicinal beers charged with hops, scurvy-grass, horse-radish, pine-buds, Peruvian bark, and called "tonic," "antiscorbutic" beers, preparations very little used, at least in France.

The third group of alcoholic beverages comprises distilled spirits and aromatized liquors. The consumption of these liquors is everywhere on the increase. In some years it has been enormous, and there is no reason as yet to predicate a decreasing ratio. In France the quantity of pure alcohol consumed in 1850 was five hundred and eighty-five thousand two hundred hectolitres; the past year it has been four times that amount, or almost two million hectolitres.

All the efforts put forth by the various governments to stay the increase in the use of distilled liquors have thus far failed. Increased taxation of spirits, severe penalties against drunkenness, diminution in the number of grog-shops, none of these things have availed. The temperance societies themselves, notwithstanding the augmentation of their membership, and notwithstanding the rigorous exclusion of every kind of alcoholic beverage, have done but little to retard the progress of intemperance. I am assured, however, that this statement is not strictly true as applied to some parts of the United States.

We see in this almost universal spread of drunkenness one of the saddest facts connected with the age in which we live.

The alcohols due to fermentation constitute a natural chemical series, of which the formulæ go on increasing from ethyl alcohol to amyl alcohol, thus:

Ethyl alcohol,  $C_2H_5O$ ; propyl alcohol,  $C_3H_7O$ ; butyl alcohol,  $C_4H_9O$ ; amyl alcohol,  $C_5H_{11}O$ .

In the work undertaken by Audigé and myself "On the Toxic Power of the Alcohols,"\* we showed that the degree of toxicity of these bodies followed in almost a mathematical ratio their atomic formula, and the following tables which I place before you sum up the results which we obtained in our first experiments which pertained to acute alcoholism.

TABLE A.—DEGREE OF TOXICITY OF THE PRIMORDIAL ALCOHOLS.

Group of alcohols.	Designation of the alcohols and their derivatives.	Medium toxic doses per kilogramme of weight.	
		In the pure state.	In the state of dilution.
		Grammes.	Grammes.
Alcohols of fermentation.	Ethyl alcohol ( $C_2H_5O$ ).	8.00	7.75
	Propyl alcohol ( $C_3H_7O$ ).	2.90	3.75
	Butyl alcohol ( $C_4H_9O$ ).	2.00	1.85
	Amyl alcohol ( $C_5H_{11}O$ ).	1.70	1.50
	Chemically pure methyl alcohol ( $CH_3O$ ).	.....	7.00
Alcohols not of fermentation.	Ordinary wood spirit.	.....	5.75
	Enanthyl alcohol ( $C_7H_{15}O$ ).	8	
	Cetyl alcohol ( $C_{18}H_{37}O$ ).	7.50	
Iso-alcohols.....	Iso-propyl alcohol ( $C_3H_7O$ ).	.....	3.70 to 3.80
Poly-atomic alcohols.	Glycerin ( $C_3H_5O_3$ ).	.....	8.50 to 9.00
Derivatives of alcohols.	Acetic aldehyde ( $C_2H_4O$ ).	.....	1.00 to 2.00
	Acetic ether ( $C_4H_8O_2$ ).	.....	4.00
	Acetone ( $C_3H_6O$ ).	.....	5.00

TABLE B.—DEGREE OF TOXICITY OF THE ALCOHOLS OF COMMERCE.

Ethyl alcohol and the alcohols of commerce.	Medium toxic dose, which, per kilogramme of the weight of the dog, will kill within 24 or 36 hours.	
	Crude spirit.	Rectified.
	Grammes.	Grammes.
Ethyl alcohol (dilute).....	7.75	
Fine wine spirit of Montpellier.....	7.50	
Brandy made from perry (by distillation)...	7.35	
Cider brandy, and that obtained by distilling the marc of grapes.....	7.30	
Alcohol obtained from grain.....	6.95	7.15
Beet spirit.....	6.90	7.15
Potato spirit (whiskey from distillation of potatoes).....	6.85	7.10
Potato whiskey, ten times rectified.....	.....	7.35

These results have been entirely confirmed by another series of researches, which lasted more than three years, and which pertained to chronic alcoholism, the subjects of the experiments being hogs. All these results may be summed up in this one sentence,—*the higher in the series the alcohol, the more toxic it is.*

All the spirits in common use contain variable proportions of the different alcohols of the series; but while wine spirit possesses but feeble quantities of propyl, butyl, amyl alcohols, as Ordonneau has shown, potato and grain spirit contain these higher alcohols in excess, and they can only be removed by successive rectifications.

Ordonneau, in an interesting work on the composition of distilled liquors, has brought to light this interesting fact, that the nature of

\* Dujardin-Beaumetz and Audigé, "Experimental Researches on the Toxic Power of the Alcohols." Paris, 1886.

the spirit produced in a fermenting solution depends on the ferment employed. If the ferment is impure, there are generated iso-alcohols, while with a pure ferment you obtain the true alcohols. Despite the identity of formula which exists between the iso-alcohols and the alcohols properly so called, the toxicity of the former is much greater than that of the latter.

Manufacturers of spirits have of late found that certain amylaceous substances, and especially rice and maize, under the action of a pure ferment, such as that high malt yeast which we use in making galazyme, give origin to ethyl alcohols of almost absolute purity, not even needing rectification, so minute are the proportions of the more toxic alcohols (potato, butyl spirit, etc.).

Pure or absolute alcohol is only of interest chemically. Rectified spirit is alcohol with sixteen per cent. of water, sp. gr. .838. Proof spirit consists of an admixture, in nearly equal proportions, of alcohol and water, and the distilled liquors sold for ordinary consumption are intended to be of about this strength.

The following table shows the richness in alcohol of different commercial spirits :

	Alcohol.	
	By weight.	By measure.
British proof spirit contains.....	50	57
Commercial cognac " .....	...	50 to 54
Rum " .....	...	72 to 77
Gin " .....	...	50
Whiskey " .....	...	59
Rectified beet spirit " .....	...	94

Since the phylloxera has made such ravages with our vines, France, which, in its vine-growing departments, as Charentes, used to produce the best brandy in the world, has suffered such a falling off in the production of this spirit that one must to-day be a millionaire to be able to afford good brandy for his table ; nor are we even sure of obtaining good brandy by paying twenty francs per litre for it.

But the brandy made from wine has been replaced by beet and grain whiskey, to the great detriment of the consumer. By referring to the table which I have given you,\* you will see that if in 1875 France produced 348,723 hectolitres of brandy, in 1879 the quantity was only 4929 hectolitres, and 13,073 in 1882. These figures show pitifully when placed by the side of the 2,000,000 hectolitres of alcohol which we consume in France.

By the side of these spirits we must place

the "liquors" of the retail shops and "cafés." The quality of these "liquors" depends on the kind of alcohol employed and the substance with which they are aromatized. Unfortunately, the flavoring ingredients introduced generally only serve to disguise the bad taste and bad quality of the alcohol used, and this is what happens in the case of low-priced liquors, and in particular of absinthe. As for the pretended stomachic and aperient substances with which the liquors of our drinking-saloons are "doctored," they have no healthy stimulant effect on the digestion, and all the bitter extracts, gentian, quassia, aloes, absinthe, etc., which, added to the whiskey or rum, constitute the basis of popular "bitters," have no favorable action whatever on the secretion of gastric juice, but rather retard and arrest it, as Tschelzoff, one of Prof. Botkin's clinical chiefs, has recently shown.† Those that think that they have derived benefit from them, in all likelihood have confounded the cramps of the stomach, which they may have experienced under the irritant action of these liquors, with the sensation of hunger.

I have finished this long enumeration of alcoholic beverages, and I shall conclude by saying a few words about the physiological action and digestibility of alcohol.

Alcohol is of itself an irritant, and, when applied to mucous membranes, it develops a sensation of heat and burning, which is the greater the more concentrated the alcohol. When introduced into the stomach, besides the symptoms of irritation, it occasions an exaggeration in the acidity of the gastric juice. The experiments of Charles Richet on Marcellin are very demonstrative of this fact.

In the normal state the acidity of Marcellin's gastric juice was represented by 1.3 gms. of hydrochloric acid per litre. During digestion the acidity rose to 1.7 gms. ; but as soon as an alcoholic stimulant was introduced the acidity went up to 2.7 gms., and even 4 gms. per litre.

This is a capital point in the physiology of alcohol as far as its influence on digestion is concerned, and this property is utilized to a certain extent in all countries, and especially in Normandy, where it is a common custom to "make a hole," as they call it, in the middle of a meal by drinking a small glass of

† Tschelzoff, "On the Influence of Bitters on the Digestion and Assimilation of Albuminoid Matters" (*Centralblatt für die Medicinischen Wissenschaften*, 1886, No. 24).

\* Omitted from the translation.

brandy. In this way the acidity of the gastric juice is augmented, and the stomachal digestion is increased. From this fact there arises an important indication,—to give to patients affected with dyspepsia from want of secretion of gastric juice a small glass of liquor after their meals.

But it will not do to prolong this action of the alcohols, for little by little the pepsin-glands become worn out and cease their functions, to give place to the increased secretion of the mucous glands. All our alcoholic dyspeptics go through about the same history. There is, first of all, gastric irritation with pyrosis, resulting from the exaggerated acidity of the gastric juice, then these symptoms give place to gastrorrhœa, characterized by the petuitous vomiting and dyspepsia of drunkards.

Alcohol, when ingested, is absorbed by all parts of the digestive tube, but especially by the intestines. It is taken up by the radicles of the portal vein, and passes into the hepatic circulation, where its presence determines portal periphlebitis, the origin of the cirrhosis of drunkards. Then it enters the general circulation, to be eliminated by the lungs and kidneys, whether in the state of unchanged alcohol or in that of acetic acid and aldehyde.

Many hypotheses have been put forth as to the physiological action of the alcohols. It is one of the most interesting of medico-physiological questions, of which I can only sum up here the leading points.

All these hypotheses may be reduced to two. The first is the theory maintained since 1860 by Lallemand, Duroy, and Perrin, which affirms that alcohol is neither transformed nor destroyed in the organism, and that the total quantity being eliminated unchanged, it cannot be considered a food. The other theory is that supported by my regretted master, Bouchardat, who claims that alcohol undergoes combustion and transformation in the economy, and therefore acts the part of a food. This is the view which I hold, and which I have defended to the best of my ability the past two years before the Academy.

You put together, I have said, in the circulating blood two chemical bodies, the one alcohol, having a strong affinity for oxygen, the other hæmoglobin, ready to yield up its oxygen under the most feeble influence, that of an inert gas, for instance, and you pretend that no exchange takes place between these bodies. Exchanges do take place, and I have

demonstrated with my pupil, Jaillet, the transformation *in vitro* of alcohol into acetic acid under the influence of hæmoglobin. I believe, then, fully in the combustion of a part of the alcohol ingested, and this combustion takes place at the expense of the oxygen of the hæmoglobin of the blood-corpuscles.

This view, moreover, finds confirmation in the experiments of Bandot, Schalin, Anstie, and Lauder Brunton, of Lussana, and Albertoni, all of whom have no doubt as to the combustion of a portion of the alcohol ingested.

So, then, to sum up my view as to the physiological action of alcohol, I should say that when introduced into the economy in non-toxic dose, a certain part of the alcohol is oxidized and is transformed into acetic acid, then into alkaline acetates, then into carbonates. Alcohol is, then, a food, but a waste-restraining food, which, instead of energizing the combustions, slows them, by robbing the blood-corpuscles of a certain quantity of oxygen. It is this action on the blood-corpuscles which explains to us the antithermic power of the alcohols, an action which attains its maximum of intensity when toxic doses of alcohol are administered. In such toxic cases the alcohol is no longer burned, but destroys the globules and dissolves the oxyhæmoglobin. Ordinarily, not all the oxygen ingested undergoes combustion. A part unchanged acts directly on the cerebro-spinal axis, and there determines phenomena of intoxication, of sleep, and of vaso-motor modifications, varying according to the quantity of alcohol ingested.

These three properties—alimentary, antithermic, and tonic—have made alcohol one of the most powerful agents of the antithermic treatment of disease, and I shall not here take your time in enumerating the numerous applications of alcoholic stimulants to medicine. I cannot do better than refer you for a vigorous handling of this whole subject to the thesis of fellowship of my former pupil, Prof. Grancher, "On the Tonic Medication," a thesis published in 1875. This finishes what I have to say about an agent which has a prominent place in hygienic therapeutics.

All the beverages considered in this lecture are taken at meal-time or between meals (the principal consumption is at meal-time), and the greater or less abundance ingested has a decided influence on the volume of the digestive tube. Dancel, basing himself on the fact that in veterinary practice one may augment or diminish at pleasure the dimensions of the

horse's stomach by augmenting or diminishing the quantity of water which the animal is allowed to drink, has also shown that it is the same with man; hence he would limit to half a pint the quantity of liquid which a corpulent person ought to take with his meal. Schweninger has gone further, and has suppressed all drinks from the dietary of obese patients, and he recommends that such persons shall not drink till two hours after meals. In the next lecture, when I come to the treatment of obesity, I shall take up this point again.

This abstinence from liquids, which has been described under the name of *the dry diet cure*, and which Fonssagrives calls *xerophagia*, has been also applied to the treatment of dilatation of the stomach. Hippocrates, Petronius, Asclepiades, and Muller had always pointed out the advantages of a dry diet in the case of serous effusions, and when there was an indication to dry up certain exaggerated secretions. This regimen has been revived in our time by Chomel in the treatment of what he improperly calls *the dyspepsia of liquids*, and by Huchard in combating dilatation of the stomach. In cases of gastrectasia, in fact, the allowance of liquids ingested augments the stomachal dilatation; hence there is every reason for restricting the quantity of drinks.

I have now concluded what I had to say concerning the principal elements of hygienic therapeutics, it remains for me to apply these data to the study of Dietetics; this is what I shall attempt to do in the next lecture.

#### A CONTRIBUTION TO OUR KNOWLEDGE OF FEVER, AND THE AGENTS WHICH PRODUCE OR ARREST IT.

BY DRs. H. C. WOOD, E. T. REICHERT, AND HOBART A. HARE.

(Continued from page 678.)

#### PART III.—ANTIPYRETICS.

##### QUININE.

THE first drug having alleged antiperiodic properties which we attempted to study was quinine. It is so notorious that this alkaloid has, unless in poisonous doses, no effect upon the temperature of the normal animal, that we do not think it necessary to record our experiments upon such animals in detail; if the bodily temperatures recorded in the table on page 734 are consulted, they will be found to confirm the general belief

that quinine has no positive constant action upon the bodily temperature in health.

The following experiments were made in order to determine the effect of quinine upon the fever produced by injection of pepsin.

#### Experiment 35.—

Time.	Remarks.
12.30.	Injected 6 grammes of concentrated pepsin into jugular vein of dog; ten minutes later injected $\frac{1}{2}$ gramme of quinine.

Time.	Rec. temp.	Remarks.
1.20	101.4°	
4.20	105.3°	

#### Experiment 36.—April 24, 1884; dog; weight, 14.6 pounds.

Time.	Rec. temp.	Remarks.
11.25	102.8°	Injected 4 grms. of concentrated pepsin.
3.30	106.8°	Injected 1 gramme of quinine.
4.35	105.6°	
5.52	103.7°	

#### Experiment 37.—Dog; weight, 9 pounds.

Time.	Rec. temp.	Remarks.
11.30	102°	
12.	.....	Injected 2 grms. concentrated pepsin. Dog etherized.
12.20	101.2°	
3.15	106°	
4.50	104.2°	Injected 1 grm. quinine hypodermically.
6.05	104.2°	

#### Experiment 38.—Dog; weight, 26 pounds.

Time.	Rec. temp.	Remarks.
11.35	103.5°	5 grammes pepsin.
12.05	102.2°	1 gramme quinine hypodermically.
2.10	102.4°	

#### Experiment 39.—Dog; weight, 6.5 pounds.

Time.	Rec. temp.	Remarks.
11.30	102.8°	
3.15	103.2°	Injected 1 gramme pepsin.
3.20	.....	Injected hypodermically 0.5 gramme quinine.
3.30	102.7°	
5.00	103.4°	
7.00	103.1°	

These experiments, in accord with those to be detailed hereafter, indicate that quinine has a distinct influence in abating the fever produced by the injection of pepsin, but that this influence is not dominant and is not shown at all unless the dose of quinine used be large. The alkaloid appears in the dog as in the man to be an antipyretic, reducing temperature when circumstances favor it, but unable to assert itself at all times.

The next series of experiments were directed towards determining if possible the action of quinine upon heat production and heat dissipation.

*Experiment 40.*—Dog; weight, 25.50 pounds.

Time.	Rec. temp.	Cal. temp.
2.52	103.6°	66.80°
3.52	104.2°	69.01°
4.00	Injected 15 grains of quinine. 2.21°	
Time.	Rec. temp.	Cal. temp.
4.20	104.2°	68.45°
5.20	104.3°	70.04°
		1.59°

An examination of the experiments and of the tables in which they are summarized will show that the results which we have obtained by the use of quinine given are not concordant. In twelve experiments there was a decided increase in both the production and dissipation of animal heat. In two experiments both functions were decidedly lessened; in one there was a slight diminution, and in two there was no distinct effect. The discrepancies are not to be explained by the varying size of doses, because contrary results were reached with doses of practically equal proportionate size.

The difficulties which attend the administration of quinine are excessive. When given by the mouth, it is very apt to vomit the animal, and if it be used hypodermically, it produces an amount of local irritation which has an immediate effect upon the heat functions. Further, our experience has also shown that there is in the uninjured animal from hour to hour a curious and at present not altogether explicable variation in the production and dissipation of animal heat, and that in order for any drug or operative procedure to produce an apparently uniform result, it is essential that its influence be overwhelming. In the present case we can only consider that the ordinary average effect of quinine given to the normal dog in the method we have used it is to produce an increase both of production and also of dissipation of animal heat. The two functions are so connected with one another that in the normal animal they must perpetually react. Anything which increases heat dissipation primarily, secondarily will increase heat production, by virtue of the fact that whenever bodily temperature is lowered by excessive loss of heat the attempt is made to maintain the bodily temperature by an excessive production of heat. Without more light than we have upon the problem, it seems to us impossible to decide whether the heat production or the heat dissipation is the function primarily affected by quinine.

We have made a few experiments upon the action of quinine on the heat functions of animals which were under the influence of pepsin. The quinine was given after the pepsin fever had commenced, but, as it is uncertain what the undisturbed course of the fever would have been had the quinine not been given, it is very difficult to judge of the exact bearing and value of our results. For this reason we soon abandoned the method of experimenting, but the results we did achieve

seem to us to accord with those obtained by a better plan.

In the following experiments the dog was first given pepsin, and after the fever had set in quinine, or else the quinine and pepsin were given simultaneously.

*Experiment 50.*—Dog; weight, 9 pounds.

Time.	Remarks.
11.30	Rec. temp. 102° F. Etherized; jugular exposed.

An examination of these experiments, as tabulated on page 737, will show that the following comments upon them are correct. In the first, Experiment 50, the temperature of the animal had been raised by means of pepsin from 102° to 106° when the first attempt was made to measure the heat produc-

tion and heat dissipation for an hour. As it turned out, the animal was just at the maximum of the fever, so that the temperature fell spontaneously nearly two degrees during the hour in which the dog was in the calorimeter. The quinine was then given, but it failed to have any effect upon the temperature, which in the subsequent hour remained constant. There was, however, a decrease in the production of animal heat so slight as to have no significance with a pronounced decrease of heat dissipation. We do not think that any conclusion can be drawn from this experiment.

In the second experiment (Experiment 51) the heat dissipation and production were first studied after the fever had been fully formed, whilst the temperature was still rising; the quinine was then given, and studies made of the thermic functions during the steady fall of temperature which followed. In both the periods examined the fall of temperature was undoubtedly the result of diminished heat production with, in the last period, marked increase of heat dissipation: if these phenomena were produced by the quinine, and were not simply spontaneous phenomena of the fever at the time when it was naturally abating, they would indicate that quinine reduces the bodily temperature by decreasing the bodily production of heat, and also increasing its dissipation. It is plain that in such case the alteration in one function is not the cause of the change of the other function, for, if it were so, diminished heat production should be accompanied by diminished heat dissipation, or else an increased heat dissipation by a decreased heat production.

In Experiment 53 the pepsin and quinine were given hypodermically, and the result was a very marked fall of the temperature, followed by a partial recovery. The fall of temperature was chiefly the result of a decreased heat production, which was only partially compensated by a parallel, but less pronounced decrease of the heat dissipation. The fall of heat production must have been primary, because it was so much larger than the lessening of heat dissipation.

It will be seen that the three experiments which we have just discussed agree in indicating that quinine in pepsin peptone fever lowers the bodily temperature by decreasing the production of animal heat. The value of the evidence may be variously estimated, but certainly the last two experiments are of some importance as evidence, although they are, of course, not sufficient to establish any theory

or generalization. After having performed these various experiments, it became plain to us that the only satisfactory method of studying the action of quinine upon peptone fever would be to produce fever in a dog by the use of pepsin in fixed amount, and, after the animal had recovered, to administer the same amount of pepsin along with quinine, and then compare the two results. Of course such experimentation is very laborious, involving two whole days for each experiment.

The results of these experiments are summarized in the following two tables. The first of these tables represents the heat dissipation of the days, giving at the same time the rectal temperature for each period, and thereby enabling the examiner to see at a glance the whole matter. The second table is similarly arranged for heat production.

In order to facilitate the understanding of these tables, which are necessarily somewhat complicated, we have prepared two small tables in which the final results are placed in juxtaposition for comparison. In the first table, heat dissipation is considered. The first column gives the number of the experiment; the second and third columns are devoted to the first day,—*i.e.*, the day in which pepsin was alone used; absolute increase and the percentage of increase of heat dissipation in the first and second periods after the injection of the pepsin being placed in their respective columns; or, as in the case of Experiment 2, the absolute increase and the percentage of increase in the only period studied after the injection of the pepsin is given in each column. The last two columns of the table represent the second day, in which pepsin and quinine were both administered.\*

A table of heat production has also been prepared for these experiments in a manner similar to that just explained.

Perhaps these tables will be most easily understood by reading one of them across. For this purpose let us take the table of heat production and read Experiment 55, as follows: The first period after the injection of the pepsin alone, the heat production as compared with that before the giving of the pepsin was increased 11.8 units per hour, or seventeen per cent. In the second calorimetric period during the pepsin peptone fever, the production of heat was increased absolutely 57.2 units, or fifty per cent. On the second day after the simultaneous administration of pepsin and quinine the heat production, as compared with that before the administration of the drugs, was increased in the first calorimetric period absolutely 4.15 units, or 4.5 per cent. In the second period it was diminished absolutely 20.45 units, or twenty-four per cent.

In examining these tables it will be found that in regard to heat dissipation the results are not absolutely concordant, but still agree

very closely. In Experiments 55 and 56 both the amount and the percentage of heat dissipation after the use of pepsin and quinine was

very distinctly less than after the administration of the pepsin alone. In the third experiment there was a slight absolute and percent-

age increase of heat dissipation during the first calorimetrical period after the exhibition of the pepsin and quinine as compared with the corresponding period of the pepsin day. But during the last calorimetric periods of the two days the dissipation was greatly less after the pepsin and quinine. The experiment taken as a whole agrees with the others. The three experiments therefore show that the addition of quinine to the pepsin causes a distinct lessening of the heat dissipation.

In regard to heat production the results achieved were similar to those obtained by heat dissipation. If the whole term of the experiments be considered in each of the three experiments, heat production was distinctly reduced by the quinine. In the third experiment, however, during the first calorimetric period after the pepsin and quinine, the increase of heat production was slightly greater than that which occurred in the corresponding period after the pepsin alone.

These experiments are in accord with those which we have previously detailed in regard to the action of the quinine in the pepsin peptone fever of dogs. We do not think that our results are sufficient to positively determine whether the heat production or the heat dissipation is the function which is primarily influenced.

In the large doses in which quinine was employed in these experiments it is well known to produce marked depression of the circulation. We have attempted to make experiments to determine, if possible, the relations between this depression of circulation and the effect of the quinine upon the bodily temperature of the fevered dog. In order to do this it seemed essential that the quinine should be injected directly into the venous circulation, as otherwise it would be necessary to wait for an hour or so for the absorption of the quinine with the animals connected with the kymographion, and not under the influence of any narcotics. In every experiment in which we have practised the intravenous injection the quinine has produced death in a few moments by its depressing cardiac influence, although the solution of the drug was well diluted, and thrown into the vein very slowly and with great caution. We have, therefore, been baffled in our attempt to study the relation between the actions of the drug upon thermogenesis and upon the circulation. We have not pushed this subject as far as we otherwise would have done, because we believe that it is an assured fact that there is a depression of the circula-

tion at the period when the bodily temperature is depressed. Whether the influence of the quinine upon the temperature can be produced by doses so small as not to affect the circulation remains uncertain, and it is still more uncertain whether the influence of the quinine upon the fever temperature is or is not due to its action upon the circulation, but we are inclined to believe in the independence of the two actions.

Quinine influences the nervous system in a manner which is, at present, mysterious; leaving out of sight the question of its antimalarial effects, its power of restoring failing uterine contractions in parturition, with its lack of power in originating such contraction, is at present inexplicable. The best explanation we can at present give is, that quinine seems in some way to stimulate or support the nervous centres against certain morbid agents and certain conditions of exhaustion, and that the uterine contractions are restored by the power of the uterine nervous centres being in this way recuperated. It is possible that the influence of quinine in fever is of similar character, or, in other words, that its chief value is due to its so stimulating or restoring the normal tone of the centres, which are connected with thermogenesis, so as to enable them to resist the morbid fever-producing influences.

In coming to this as a plausible conclusion, we, of course, do not mean to assert that we have fairly established it experimentally. It is equally possible, and perhaps, to most minds, it may seem a more probable conclusion, that the influence that we have found quinine to possess over the heat functions in fever is due to a power similar to that which we shall show later in this chapter is exerted by antipyrin.

(To be continued.)

#### ON THE USE OF ARSENIC IN CERTAIN FORMS OF ANÆMIA.\*

BY WILLIAM OSLER, M.D.†

**I**N an address last year, Dr. Wilks remarked that in therapeutics we do not so much need new remedies as a fuller knowledge of when and how to use the old ones. I do not know a more striking illustration of this than

\* Read before the Philadelphia County Medical Society, September 22, 1886.

† Professor of Clinical Medicine in the University of Pennsylvania.

is afforded by arsenic, a good old remedy, for which an almost new use has arisen in certain cases of pernicious anæmia. The attention of the profession was directed to the subject by Bramwell in 1877, and although various reports bearing witness to the value of this drug have appeared from time to time, the knowledge of its efficacy does not appear to be very wide-spread, and there are still points in connection with its employment upon which we need information. These, I trust, discussion may bring out, and render clear the direction which future observation should take.

In treating a case of anæmia, it is of the first importance to ascertain, if possible, the cause. For convenience, and until the present complex pathology is simplified, we may classify the anæmias into secondary and primary; the former induced by causes acting upon the blood itself, the latter the result of disturbance in the blood-making organs. This distinction, not always clear, serves to separate two clinical and pathological groups of cases.

The secondary anæmias are the most common, and arise from a variety of causes, as hemorrhage, prolonged drain of albuminous material in chronic disease, and the action of toxic agents in the blood. In very many of these conditions a return to the normal state follows naturally upon removal of the cause, and the regeneration of the corpuscles may take place with extraordinary rapidity, as after a copious bleeding or a sharp fever; but, as a rule, iron in some form will be found useful or indispensable. In three of these secondary anæmias I have found arsenic very beneficial.

1. *The Anæmia of Heart-Disease.*—In chronic valvular trouble we not infrequently meet with an impoverished condition of the blood, which materially aggravates the cardiac distress. The comfort of such patients is in direct proportion to their corpuscular richness, and without any apparent increase in the valve mischief, a reduction in the ratio of the corpuscles is followed by shortness of breath, palpitation, and signs of heart-failure. The value of iron in this condition is well known, and its combination with digitalis a universal practice. Arsenic is also indicated in these cases, particularly in children, or if, as sometimes happens, iron does not agree. In June of this year I saw a lad, J. W., æt. 14, who had had chronic valve-disease for four years. He had been wintering in the South, and went afterwards to the Arkansas Hot Springs. When I saw

him the anæmia was very marked, and he suffered from breathlessness on the slightest exertion. There was no cardiac distress, and the compensation was not seriously disturbed. At the Hot Springs he had several chills, with fever, for which he had taken quinine. He was ordered Fowler's solution of arsenic, beginning with  $\text{m} \text{iii}$ , three times a day, and increasing to  $\text{m} \text{vi}$ , if well borne. He had been taking an iron and strychnine pill for several weeks, and had with him a boxful, which he was advised to finish. Digitalis was prescribed, but was not to be taken unless there were signs of heart-failure. The diet was carefully regulated. The lad improved rapidly, and within six weeks had a good color, and had gained several pounds in weight. He had not needed the digitalis. The arsenic was well borne. The improvement had continued on the 3d of this month. Possibly here there was a malarial taint; but, in any case, if medicinal agents had anything to do with the rapid improvement, the credit is due to the Fowler's solution.

2. *In Malarial Anæmia.*—The value of arsenic in chronic ague-poisoning is so well recognized that I need scarcely detain you with the narration of cases in support. There have been several at my clinic during the past year in which the improvement in the blood condition, as tested by the hæmacytometer, has been very remarkable. One case in particular, from Cape May, I may refer to, as the patient, with enlarged spleen, had on two occasions hemorrhage from the stomach. The arsenic in this case was pushed for several months in increasing doses. At one time he took  $\text{m} \text{xxxvi}$  of the Fowler's solution daily. When last heard from, in July, he was at work, and had gained in flesh and strength. On May 12, the date of the last blood count, the percentage was over eighty (it had been scarcely fifty), and the spleen had diminished materially in volume. In certain of these cases the ratio of the corpuscles may increase rapidly without any essential change in the volume of the spleen. In the case of M. D., a girl of 15, who has been in the University Hospital on several occasions for the past two years, the arsenic, which was very persistently employed, does not appear to have reduced the spleen in the slightest degree, and yet under its use the corpuscles rose to eighty-five per cent. In this instance, with a history of malaria, there is evidence also of congenital syphilis, to which may possibly be due the splenic enlargement. Injections of arsenic

into the substance of the organ were tried without benefit.

3. *Certain Anæmias of Gastric Origin.*—As a tonic in debilitated states of the stomach, arsenic has long been a favorite remedy with many practitioners. It is sometimes also of great service in the anæmia of chronic gastric catarrh, particularly in alcoholic patients. A good illustration of this was under my care at the Philadelphia Hospital this spring. W. G., aged 25; waiter; hard drinker; history of dyspepsia for several years. Admitted April 5 with anæmia and attacks of giddiness. Ill for ten days; vomiting, pain in stomach, and fainting spells on attempting to stand. Had been failing in strength for some time and getting pale. Had suffered from palpitation, and said he had vomited blood. He was profoundly anæmic, and could not stand without danger of fainting. Tongue coated; great irritability of stomach; vomiting on the slightest provocation; great throbbing of abdominal aorta. He was kept at rest, given a milk diet, and Fowler's solution in 3-drop doses. The red corpuscles were not more than twenty-five per cent., and the coloring matter about the same. The improvement was rapid, and by the 21st the corpuscles had risen to over forty per cent., and the gastric irritation had almost disappeared. The arsenic was well borne, and was gradually increased to  $\text{xxvii}$  t. i. d., and on May 4 he was ordered small doses of nitromuriatic acid. On May 17 he left the hospital with a fair digestion and, for him, tolerably good color. On June 24, when readmitted with extensive pleuro-pneumonia, he stated that he had recovered strength rapidly, and had been at work. Possibly, in this case, there was ulceration of the stomach in addition to the chronic catarrh; but, whatever the condition, it was one in which the arsenic seemed to be highly beneficial, and, as he received no other medication, we may reasonably attribute to it the stimulation of the blood-making function. As we shall see, there are anæmias of gastric origin in which this drug is powerless. These are some of the secondary anæmias which have, in my experience, been apparently benefited by the use of arsenic.

Turning now to the primary group, we have here again for convenience to make a division of the cases. There is, first, a large section of what may be called cytogenic anæmias, in which the reduction and alteration in the corpuscles is associated with evident changes in the hæmatogenous tissues,—the spleen,

lymph-glands, and bone marrow. Sometimes these changes are accompanied by an increase in the colorless corpuscles of the blood; and, depending on the organ involved, we then speak of splenic, lymphatic, or medullary leucæmia. If there is no marked increase in the white corpuscles we call the cases splenic anæmia, lymphatic anæmia (Hodgkin's disease), and medullary anæmia. The pronounced leucocytosis in certain of the cases, which gives a special character to the blood, is probably not such an important factor as we have hitherto supposed, and there are such insensible gradations between the cases that in a strict classification they may be appropriately grouped together. Secondly, there is the curious primary anæmia known as chlorosis, characterized by well-marked etiological and anatomical peculiarities; and, thirdly, we have the much-discussed affection, pernicious or essential anæmia.

The anæmias of this primary group offer a remarkable therapeutic study, embracing cases of the most hopeful and the most hopeless character. A clearer knowledge of the etiology and pathology of certain of these forms may give a clue to lines of treatment more fortunate than those we now possess; for, if we except chlorosis, the majority of the cases of this class of anæmias prove fatal. Leucæmia, splenic anæmia, when non-malarial, Hodgkin's disease, are considered incurable affections, and very many of the cases of pernicious anæmia prove obstinate to all treatment.

The relation of arsenic, as a remedy, to this group of primary anæmias is worthy of our closest study, more particularly as of late years remarkable results have been reported from its use. Chlorosis may here be excluded from our consideration, as it would only be in a strangely obstinate case that a practitioner would require to employ arsenic. The specific action of iron in increasing the defective hæmoglobin of the corpuscles, and doubtless, also, in stimulating the formation of new ones, is one of the few instances in therapeutics in which definite tissue-changes, under the influence of a drug, may be followed with scientific accuracy from day to day and from week to week.

In *leucæmia* and *Hodgkin's disease* arsenic has been extensively tried, occasionally with temporary success. We must bear in mind in these affections that there are natural periods of improvement without any special medication. I have met with this in leucæmia, and it must be taken into account in our estimation of the effect of a remedy. Person-

ally, I have not seen any benefit from the use of arsenic in this disease. It was given in several of the eleven cases which I saw in Montreal, all of which were fatal. In Hodgkin's disease the report is more favorable. In 1883 I had two cases, both in women, in which the large glands of the neck and armpits reduced materially under the prolonged use of Fowler's solution, but I do not know the subsequent history of the cases. Several writers have reported most satisfactory results. Karsowski\* had three recoveries, and of eleven cases treated at the Stockholm Hospital five were benefited.† The persistent use of it in full doses for many months is probably the most efficacious remedy we possess in this disease.

In cases of *splenic anæmia* of non-malarial origin, I cannot say that I have seen any special benefit from arsenic.

We come now to *pernicious anæmia*, in which so much has been gained by the judicious use of this drug. Pernicious anæmia includes cases of very diverse etiology. Any severe anæmia tending to a fatal termination may well be termed progressive and pernicious. In a considerable proportion pregnancy and parturition appear to have been determining factors, while others can be directly traced to defective food, as in many of the Zurich and Bern observations. Excluding these, we have a group of cases of which the etiology is obscure, and to which, in our present knowledge, the terms *idiopathic* of Addison and *essential* of Lebert are applicable. Every year, however, we are reducing the number of cases which we can strictly call idiopathic. It is reasonable to suppose that the extensive changes in the bone marrow found in certain instances are directly related to the profound disturbance in blood formation, just as is the case in hyperplasia of the spleen or of the lymph-glands. An anæmia medullaris is now very generally recognized. Then, there are the cases of pernicious anæmia in which the primary disturbance seems to be in the gastro-intestinal canal, and the condition of the blood the direct consequence of the impaired nutrition. There remain cases in which none of these conditions prevail, and neither during life nor after death do we find any clue to the origin of the anæmia. To such, for the time, the designation idiopathic is applicable. Clinically, it may be impossible to distinguish between these various forms,

and the etiology is often very obscure and gives us no help. The cases which come on during or after pregnancy, or which result from inanition, are readily recognized, and offer, as a rule, a more hopeful prognosis; but we cannot yet with any accuracy separate during life the cases in which there is atrophy of the mucous membrane of the stomach, or extensive medullary changes, from those in which these conditions are absent. A more careful study may in the future enable us to do so, and I have laid stress upon these differences in etiology and pathology because in them will possibly be found the explanation of the success or failure of certain remedies.

Prior to 1877 arsenic was not systematically employed in pernicious anæmia, and to Bramwell is undoubtedly due the credit of its introduction. Neither Müller‡ nor Eichorst,§ in their elaborate monographs published in 1877 and 1878, speak of its use. Padley,|| in an interesting review of the question, has carefully analyzed the cases in which arsenic was not employed, and finds that of forty-eight, forty-two were fatal, while of twenty-two cases treated with arsenic sixteen recovered, two improved, and four proved fatal; and he remarks, that "in the whole list there is not, with one exception, a single authentic case of recovery in which arsenic did not form the chief part of the treatment." Certainly the reports of this affection since 1880 have been much more encouraging, and it need not necessarily be regarded as "almost invariably fatal," to use the words of a leading textbook. Of three cases of pernicious anæmia which I have seen this year two have already proved fatal, and one is in a fair way to recovery.

CASE I.—A man, aged 42, I saw with Dr. Henry. We reported it in full in the April number of the *American Journal of Medical Sciences*, and it is remarkable as an instance of pernicious anæmia, with advanced atrophy of the mucous membrane of the stomach. Arsenic was given during the course of the disease, but not for any length of time, as it seemed to bring on diarrhœa.

CASE II.—A woman, aged about 45, I saw with Dr. Weir Mitchell on January 20. She had been the subject of dyspeptic attacks for some years, and had become very pale, and during last year the anæmia reached an extreme degree. With rest, systematic feed-

\* *Berliner Klin. Wochenschrift*, 1884, 17 and 18.

§ *De Progressive Perniciosa Anæmie*. Leipzig, 1878.

|| *Lancet*, 1883, ii.

ing, iron, and arsenic she improved, and was able to go home and attend to her household duties. I saw her in January on her way South. She returned in March very much worse; was again placed on the plan of treatment which had proved so successful in the first attack, but the stomach was so irritable and the digestive power so enfeebled that she sank, and died on the 18th of April. The improvement in her first attack was attributed by Dr. Mitchell to the careful feeding and rest as much as to the medicine.

CASE III.—An active business man, aged 43; seen March 4. History of dyspepsia, and for the past six months failure in strength. Shortness of breath on the slightest exertion, and at times attacks of agonizing pain at the heart resembling angina. He had not lost much flesh; indeed, as is usual in these cases, the subcutaneous fat was well developed. When first seen, the anæmia was marked; lips and tongue very pale, and sclerotics pearly. The general surface did not look so pale, on account of his dark color and a decided saffron-yellow, sub-icteroid tint of the skin. The temperature was a little elevated; pulse 100, and of moderate volume. With the exception of heart-murmur, there were no symptoms elicited in the examination of thoracic and abdominal viscera. The blood showed in a marked manner the corpuscular changes of advanced anæmia. The blood count could not be made at the time, but when I next saw him, two weeks later, there were only 700,000 red corpuscles to the cubic millimetre, and the color percentage was only about twenty. He was put to bed, absolute rest, given a milk diet, ordered massage once a day, and as medicines bismuth and carbonate of sodium, with Fowler's solution  $\mathfrak{xxv}$ , three times a day, to be increased one minim daily at the end of a week. He had been taking, by the advice of his physician, an elixir of iron and strychnine, which was continued. For two months there was not much apparent change, though the ratio of the colored corpuscles increased to over 1,500,000 per cubic millimetre. The arsenic had been pushed to 15 drops three times a day, when puffiness of the eyelids and forehead came on, and it was omitted for a week, and started again with  $\mathfrak{xxv}$ . On reaching  $\mathfrak{xlxiii}$  a slight red rash appeared, and it was stopped, and, after beginning at  $\mathfrak{xxv}$  again, he reached  $\mathfrak{xxx}$  t. i. d. On these large doses he seemed to improve more rapidly, and he bore them for two weeks or more, when gastric irritation supervened, with diar-

rhœa. The drug was then stopped for ten days, and pills of  $\frac{1}{10}$  of a grain of arsenious acid ordered. On January 31 he was allowed to get up. By June 13 he was able to move to Cape May. The blood condition has rapidly improved, and at the last count the corpuscles were nearly 4,000,000 to the cubic millimetre. When seen on September 7 he looked remarkably vigorous, had a good appetite, was at business, and feeling very well. It would be incorrect to attribute the success in this case entirely to the arsenic, but rather to the plan of treatment, in which it was a very important factor. It will be found, I think, that absolute rest in bed, with daily massage, and the strictest attention to feeding, are most important features in the successful management of these cases.

Arsenic has been spoken of as a specific in pernicious anæmia. This is a mistake. The disease, as I have indicated, is so varied, and results from the operation of such diverse causes, that we cannot expect any one remedy to be uniformly active. In a majority of the cases iron is useless, but it sometimes succeeds after arsenic has failed absolutely. Such a case was reported by Finlay\* last year, which was cured by iron after a thorough and but ineffectual use of arsenic. I do not think we understand fully the conditions in which it is most serviceable, and for the time we must be content to employ it empirically, on faith of the success which has attended its administration in so many cases. Ultimately, we may hope to be able to discriminate between the cases which call for iron and those in which arsenic is indicated, and with this object in view the cases which come under observation should be carefully studied.

*Mode of Administration.*—I usually give the liquor arsenicalis (liquor potassii arsenitis), beginning, in an adult, with  $\mathfrak{xxv}$  three times a day. Occasionally this is found too much, and I reduce the amount to 2 or 3 minims. After ten days, if well borne, I order an increase of a minim each day, so that by the end of the second week the patient is taking 10 or 12 minims three times a day. This is kept up for a week, and then gradually increased until the physiological effects are obtained. The amount which will induce these varies with different individuals, and those who bear it best seem to improve the most rapidly. I have thought sometimes that the small doses are not so well borne as larger

\* *Lancet*, 1885, i.

ones, and are more likely to cause gastric irritation. Young people bear it remarkably well. Within the physiological effects there is no special limit to the quantity, and, as in chorea, I make them my guide in the administration. A very important point is the continuous use for many weeks or months, omitting for a few days if unpleasant effects arise. Even after apparent recovery I advise the continuance of the drug. When the liquor arsenicalis is not well borne, the arsenious acid in pills may be tried, or the solution may be given hypodermically. In these cases of severe anæmia I never care to use hypodermic injections systematically, as I have seen ecchymosis of the tissues follow, and in several instances distressing small abscesses. By the rectum, it is usually well borne.

The three points I would indicate for this are,—

1. In what secondary anæmia is arsenic beneficial, and under what conditions is it preferable to iron?
2. In pernicious anæmia what cases are benefited by arsenic? What by iron? How shall we frame rules for our guidance in the matter, or must we still work empirically?
3. In the administration of arsenic, what is the best form and method?

#### THE SALTS OF MANGANESE IN FUNCTIONAL DISORDERS OF MENSTRUATION.\*

By J. L. WATKINS, M.D., NASHVILLE, TENN.

WHEN the Committee on Essays appointed me to read a paper on the "Therapeutic Uses of Permanganate of Potassium," I had little idea of the magnitude of such an undertaking, and went vigorously to work collecting such data as I had access to, and at the same time instituting some experiments to ascertain and establish in my own mind the location of permanganate of potassium as an antiseptic, disinfectant, etc. As the work progressed, its results, whether valuable or not, grew to such proportions that it was clearly impracticable to undertake a presentation of the whole subject before you in one evening. I determined accordingly to ask your attention to only one of the many claims it has upon us as a valuable therapeutic agent, that of its use as a regulator of the

menstrual function. Nor can I undertake a very extended consideration of the manner in which it acts, as the most of my time shall be consumed in reporting cases upon which I have tried it.

Remembering how much has been written in the last three years upon this subject, and how favorable, in the main, have been the reports, I have been surprised to find, upon inquiry, how few of the physicians in this city use it; how few, indeed, know of its action as an emmenagogue.

It was in the early part of 1883, I think, that I saw Ringer and Murrell's article on the subject in the London *Lancet*. I determined at once to make a thorough trial of the remedy, and unscientifically to make it a routine treatment until I could satisfy myself as to its merits. Up to the 1st of August last I had used it in nineteen cases, of which I make the following report, giving them in the order in which they occur in my note-book.

CASE I.—One of the most striking in its results I have met with was in Mary A., Jefferson Street, a thin, consumptive-looking mulatto girl, 17 years old, who had never menstruated, who gave a history of tubercular heritage, but the disease had not actively developed itself up to the time I saw her in August, 1883. I treated her vigorously with cod-liver oil, hypophosphites, iron, exercise, etc., and while her general health and physique were greatly improved, up to January, 1884, four months later, she had failed to menstruate. My first opportunity was here presented to try the remedy for which Ringer had claimed so much. Accordingly, I ordered the permanganate in gr. ii, t. i. d., with no other directions. The next day I was summoned hastily by her mother to know if I had poisoned her daughter, so great was the distress after taking each pill. This frightened and discouraged me somewhat, but I wrote for a dozen pills composed of gr. ii ext. hyoscym. and gr.  $\frac{1}{4}$  ext. opii each, one to be taken a half-hour before each permanganate pill, and urged my patient to persevere in the use of the medicine at all hazards. She was enabled by the last prescription to better tolerate the permanganate, but still suffered from the characteristic effects of the drug,—viz., substernal pain, distressing nausea, vomiting, and griping. She stoically kept this up for ten days, at the end of which time a slight, pale flow was observed, but lasted only one day. The remedy was discontinued the next day for nearly three weeks, and then renewed. After struggling

\* Read before the Nashville Academy of Medicine, September 30, 1886.

with its bad effects for eight days, she was rewarded with a menstrual flow of no mean proportions, lasting three days. The next period the remedy was left off, and no flow appeared; it was tried again the succeeding month with satisfactory results.

Since this time she has menstruated occasionally, frequently missing, however, but refuses to take the permanganate on account of the disturbance it occasions, and because the absence of the flow does not inconvenience her as much as the medicine does.

CASE II.—Occurred about the same time, in January, 1884, in Ella B., an octaroon, unmarried, aged 20 years, with perfect physical development and excellent previous health. Had just passed a third period without menstruating; said it made her sick, and she wanted relief. I ordered permanganate of potassium, 2 grains in solution, to be taken every four hours; but she could not stand the disgusting taste, and, after the second dose, a change was made to 2 grains in pill form every four hours. My patient was admonished that she was taking a strong medicine, and that its effects would be as disagreeable as its taste. Two days afterwards, being called to see her, I found a copious flow was in progress, but accompanied by severe bearing-down pains. She had suffered for more than an hour after each dose with the most violent pains in the stomach, behind the sternum, and in the occipital region; with nausea, vomiting, sickening eructations, and great prostration. Thinking she had only dysmenorrhœa, which would be corrected by a continuance of the remedy, I insisted that she should not leave it off, and took my departure. Early the next morning I answered a hasty summons to see her, the messenger saying "something had happened." I was thunderstruck upon entering the room to be shown a well-developed three months' fœtus and placenta, which had passed a short time before, and to find the girl flooding dangerously!

I did not know as much about the race as experience has since taught me, and never suspecting pregnancy, as she was unmarried, had innocently, or rather through negligence, I fear, produced an abortion, the very thing the wretch desired. I had been caught in the trap she laid for me, but said nothing about it, stopped the hemorrhage, and left.

Dr. Ringer says permanganate of potassium will not produce abortion; but it certainly did so in this case. Whether it acted as a direct oxytocic, or whether the miscarriage

was brought about indirectly by the violence of the heaving and vomiting and the extreme prostration, I am not prepared to say.

CASE III.—Mrs. W. J. R., Church Street, aged 25 years; married three years; had only one child, which was nearly two years old. Consulted me in February, 1884, for cessation of menstruation. She was small, but round and plump, with good color. Always had good health, with the exception of occasional dysmenorrhœa or menorrhagia, accompanied by distressing headache. Like the child in the saying, I had been burned once (in the last case), and was afraid of the fire (in this one). Here was a young married woman who had weaned her child six months before, why might she not be pregnant also? My fears were soon put at rest, however. She knew she had not been "caught," as she expressed it, this time, because she had been in Louisville, away from her husband, for nearly three months, nursing her sick mother and father, the latter having just died. She had menstruated twice during the first month of her absence, and had seen nothing since; which irregularity was manifestly due to the close confinement, loss of rest, worry, anxiety, etc., incident to nursing sick and dying parents. She had just returned home two days before, and her sickness was then due, causing dragging pains in the pelvis, nervousness, vertigo, and headache. I gave her 2 grains of the permanganate three times a day after meals. The drug caused her no discomfort whatever, and she began menstruating after the fourth dose, her sickness continuing three days. In February, 1885, she consulted me for the same trouble, and was treated in the same way with equal success. Also in December, 1885, with like results. She moved to Chicago a few months since, and three weeks ago I had a letter from her asking for the same prescription, saying the change of climate had not agreed with her, and she had not menstruated since going there. I prescribed the permanganate, but have not heard from her since. In this case the remedy was remarkably prompt in its action, and caused no gastric disturbance.

CASE IV.—March, 1884. Mrs. George C., Jefferson Street, aged 37, married, but had not lived with her husband for nearly a year, he being off in another county at work. Had never borne any children; was a hard-working woman, but poorly fed; had not been perfectly regular since her marriage, and had not been sick now for four months; suffered with slight difficulty of urination, habitual constipation,

frequent and severe pelvic pains, pain in the back and left hip. She took the permanganate capsules, 2 grains each, three times a day. They produced no effect beyond that of great gastric disturbance, and were discontinued in ten days. The treatment was begun again a week before the next period, but fell short of the desired effect, as it did also the two months following. I promised her to change the treatment the next month, but she never returned. I made no examination of the patient, and cannot say precisely what was the cause of the amenorrhœa.

CASE V.—In August, 1884, attended Mrs. Lizzie K., Church Street, aged 31 years. Had been a widow two years; was the mother of two children, the younger 7 years old; had missed last two months without apparent cause, her health being very fair with the exception of an annoying nervous cough, for which I had prescribed several times without success. Two-grain capsules of the permanganate were administered three times a day, causing the usual gastric distress, but giving negative results as far as menstruation was concerned. They were discontinued in six days, but renewed four days before the next period was expected. Normal menstruation came on in due time, and she has continued regular since. The cough disappeared with the return of the menses.

CASE VI.—In July, 1884, was one of metrorrhagia in a German girl, Annie F., 19 years old. Extreme plethora was combined with a large development of the lymphatic temperament in this case. The complexion was muddy, and her puffy face disfigured by an abundant eruption of *acne pustulosa*. She was chambermaid in a German hotel, and had a good deal of scrubbing and other hard work to do. She had suffered with metrorrhagia for five months, her sickness appearing with irregularity every two or three weeks, and lasting from seven to ten days. This weakened her and rendered her so utterly miserable that work became intolerable, if not almost impossible, and she was crying nearly all the time. Wishing to give the permanganate a fair trial in this case, I prescribed it alone and sent her to the country. She returned in two days saying she could not take the medicine, it made her so sick. I imagined the extr. of hyoscyamus alone would lessen its disagreeable effects, and so ordered 2 grains of it, to be taken a half-hour before the permanganate capsules. The result was not what I hoped for, but enabled her to bear the capsules a little better. She returned from

the country to her work in six weeks, her general health much improved, and a decidedly satisfactory improvement in the amount of her flow. She had left off the hyoscyamus in four days, but had kept up the permanganate throughout the month, her sickness not appearing until twenty-four days after the cessation of the last flow, and continuing only five days.

I saw her three weeks afterwards. She was still taking the permanganate notwithstanding its disagreeable effects, and the intermediate flow had not appeared up to that time, a few days from the next period. I have never seen her since.

CASE VII.—August, 1884, Matilda H., aged 20, of German parentage, living in the country, healthy, industrious, and fond of her flowers. She got her feet wet while working in the garden, causing sudden suppression of her menses, which had just begun upon her. She was suffering so intensely with pelvic pains, headache, cold extremities, and short, rapid breathing, that I gave her a hypodermic injection of morphine and atropine. Ordered potassii permanganas, gr. ii, t. i. d. The flow reappeared satisfactorily after the fourth capsule had been taken, but the remedy was continued another day.

CASE VIII.—Mary B., single, aged 19, German cook. Her father's home in East Nashville was burned on the night of February 2, 1885. She was aroused from sleep, ran out into the cold night air without more protection in the way of clothing than she had worn in bed. The sudden exposure to cold, and the severe shock and fright she had endured, caused a suppression of her menstruation, which was then in the second day of its progress. I called to see her on the morning of the third at a friend's house, found her with a most agonizing headache, uterine pains, and chilly sensations. I ordered for her permanganate of potassium in 2-grain capsules, to be followed by two tumblers of water each time, and to be taken after meals. They gave her very little trouble, causing only a sense of fulness in the stomach, and during the next night her sickness reappeared, and lasted two days.

She consulted me in June of the same year, having gone two days over her time, with no other signs of menstruation than those of dizziness and backache. She brought with her the same box of capsules she had taken before, and asked if she must take them again. I found six of them left, and directed her to take them as she did before. Five of them

caused the menses to return, but gave her more pain in the stomach than at first.

CASE IX.—Fanny R., Hayes Street, 17 years old. Came here from the country in January, 1885, to attend school. Was tall, thin, rawboned, anæmic, with frequent swelling of the ankles, and hysterical, bordering on insomnia. Indifferent to her studies, but devoured novels with passion, and lived all the while in a morbid atmosphere of romance, dreaming and sighing. She had not menstruated in February and March, and was anxious about herself. I saw her in April, and at my first visit prescribed a pill of valerianate of zinc, belladonna, nux vomica, aloes, and iron, and 2-grain capsules of binocide of manganese, each to be given three times daily. She reported at my office, three weeks later, improved in general health, had better color, was not so nervous, and slept well, but no menses had appeared. I told her to keep up the tonic pills, but changed from the binocide to the permanganate, to be begun four or five days before the next period. This change, made without reason, cost me my patient, as she sent for me two days after she began taking the permanganate, complaining bitterly of its distressing effects upon the stomach. As I had neglected before to tell her to take it after meals, and to follow it with large draughts of water, I gave her those directions, and promised to return the day following, after assuring her she would have no more trouble. The next day she sent word that I need not come out. I suppose she had found the permanganate, with its vigorous manifestations, decidedly too unromantic for her, and had fled to the ideal realms of unreal infinitesimals. Indeed, I heard as much afterwards.

CASE X.—Mollie H., age 22, sister of Case VII., consulted me in June, 1885. Had not menstruated in two months; was to be married in September, and wanted to be all right by that time. She was of a decidedly bilious temperament and sluggish in her movements, had no appetite, was anæmic and restless at night, had frequently suffered with dysmenorrhœa. She was hired out as house-girl, and did a great deal of hard work for a large family. Put her on the 2-grain permanganate dose, to be followed by large draughts of water. This made her so sick she had to quit work and go to bed, but discontinued the medicine after the fifth dose. I accordingly changed to the binocide of manganese in 3-grain doses before each meal. She tolerated this very well, and kept it up

through July and August. Although the general health was improved, the menses failed to put in an appearance in July, but they came on in August, also in September, during which month she married and I lost sight of her.

CASE XI.—July, 1885. A simple case of suppressed menstruation in Matilda L., a German girl, 20 years old, caused by taking a cold bath while sick. The function was restored by a few doses of permanganate capsules, followed by large draughts of water, and no unpleasant effects from the drug.

CASE XII.—July, 1885. Mrs. John M., Gallatin Pike, 32 years old; a small, frail woman. Had never menstruated or borne children during the ten years of her married life. Suffered almost constantly with pain in the back, pelvis, and left hip; had no discharge of any kind. Thought if she could have her menses restored she would have better health. She would not permit an examination, so I had to strike out in the dark, and prescribed the binocide in 2-grain doses three times a day. After continuing this five weeks ineffectually, she took the capsules every four hours with no better result. I then added a tonic treatment, and changed to the permanganate in 2-grain capsules after each meal with copious draughts of water. This was taken two months, was well borne, but accomplished nothing in the way of establishing menstruation. In the mean time the lady had taken on flesh, and was much improved in general health. I could not induce her to continue or to undertake another line of treatment.

CASE XIII.—Mrs. Jenny B., Hillsboro' Pike, about 38 years of age; highly nervous temperament, small, wiry figure; had been a widow several years. Was called to see her on the night of February 2, 1886; found her suffering with an aggravated form of hysteria. Had been nursing her sick father-in-law several weeks, and, on account of the loss of sleep, irregularity of habits, anxiety, etc., had passed over her last period without menstruating, and had been more or less hysterical ever since. I administered to her immediate wants that night, and told her to let me know a week before her next period was expected. On the 15th of the same month she sent for me, saying she was due on the 20th. Permanganate capsules in 2-grain doses after each meal, followed by a tumbler or two of water, were ordered. She came to my office March 1 to say the remedy had acted promptly, and had not given her the trouble I had caused her to anticipate.

CASE XIV.—February, 1886, Jennie H., laundry-girl, 21 years old, was like Cases VII. and XI., one of suppressed menstruation from exposure to cold, and was treated successfully in the same way.

CASE XV.—In February, 1886, I was called to see Amanda L., a colored girl, 24 years old, who two days before had taken on her own responsibility a nickel's worth of calomel for biliousness. How much she got I do not know, but she had to endure for the next six weeks the most horrible tortures of mercurial salivation, which passing off under treatment, left her in a most pitiable condition of anæmia and vital depression, with metrorrhagia which had lasted more or less throughout the period of the salivation, but which had escaped my notice, not having had my attention called to it. Her stomach was so weak and irritable still that I was afraid of the permanganate, but put her upon the binocide to see what effect it would have upon the too abundant flow. Four-grain capsules three times a day were ordered, and at the same time the stomach treated by appropriate remedies. I had the gratification in three weeks of seeing her well and at work again. The excessive flow had been stopped some days before, and normal menstruation came on at the next period and continued only four days.

CASE XVI.—Frances J. was brought to me by her mother in April, 1886, with the following history: She was now 18 years old, of large physique, lymphatic temperament; had been in excellent health up to her fourteenth year, since which time she has had almost constantly a dull headache, and regularly every four weeks has had epileptic convulsions, foaming at the mouth, biting her tongue, and remaining unconscious several minutes. These convulsions, always short in duration, came on at frequent intervals for three or four days, and then passed off to reappear at the next menstrual period. As she had never menstruated, the epilepsy may be easily accounted for. I put her upon the Brown-Séquard treatment for the epilepsy, and made an attempt to remove its cause by establishing menstruation with the permanganate first and the binocide afterwards, beginning in each case grain ii t. i. d., and running up to grain iii every four hours in the former, and grain iv every four hours in the latter. They made no impression whatever except upon the stomach, but were comparatively well tolerated. The headache entirely disappeared under the treatment, and the par-

oxysms were much milder but still continued. The manganese was continued until July, when they went to the country to remain all summer. I stopped it, as a thorough trial had proven it valueless in this case. Her mother would not permit an examination, she said, until other treatments had been exhausted. She returned a few weeks since in pretty much the same condition, except that there is a growing intellectual debility. She has consented for a thorough examination, which I suspect will reveal cause for more radical treatment than she has had.

CASES XVII. AND XVIII.—Two sisters, Mary H. and Sarah H. They are 17 and 19 years old; both have been chlorotic for some months, and have always been "irregular." They are large, fleshy, sluggish in their movements, and are at the same time extremely nervous. I have had them under observation over three months; the older one, though not yet well, has become less chlorotic, stronger, and more active, and the last two periods have been normal. The younger, though not so markedly chlorotic at first as her sister, has not improved in any respect. Both had the usual permanganate capsules.

CASE XIX.—Dora G., a Hungarian, unmarried, 20 years old, came under my notice August 29 for another trouble, but told me then she had suffered for some months with too much sickness. She moved here, in November last, from New York, to live with a sister; but having more friends in New York, and pleasanter occupations and diversions there, she soon grew homesick, peevish, and fretful; lost interest in everything here, and pined for friends and associations there, and lapsed from a state of menstrual regularity into a metrorrhagia. Each period would last seven days, and then there would be an interval of seven days before the next came on. One week on and one week off we might say. This had continued with unbroken regularity for nearly nine months. Dr. Jacobi, of New York, had treated her for the same condition three years ago with tinct. ferri chloridi, I judge, as she said it was a red liquid in a small glass-stoppered bottle, to be taken through a tube. This cured her in a short time, and would have done so again I suppose; but I wished to try the manganese treatment, and accordingly put her on the binocide, grain ii, in capsules, after each meal. Her last sickness passed off on the 1st, she then looked for a rest until the 8th, when she expected it to begin again and last until the 15th. She began the binocide on the 2d and is still

taking it. It produced no gastric irritation, but a slight catching pain behind the sternum occurring after each dose. She was in my office on the 21st of this month, and reported no flow since the 1st, the first time in nine months that she had passed two consecutive weeks without menstruating.

The first criticism you have to make is that I have thrown aside all reason and discretion in not selecting my cases, and the proper remedy for each case. I plead guilty, but claim method in my madness. As I stated in the beginning of the paper, I made it a routine treatment from the first, regardless of indications, that I might be enabled finally to judge what class of cases it was suited to, and what would do better under other forms of treatment.

We have seen from Case II. that it possesses more or less oxytocic effect, whether direct or indirect, and should therefore be given cautiously to married women suffering with amenorrhœa.

Now let us straighten out this mass of empiricism and see what else we can glean of value from it. And to the better accomplish this, I shall undertake to answer from my experience with the above cases the eight questions propounded by Dr. Billington, in *The Record*, in his superb paper on this subject.

"1. Is the permanganate of potassium an efficient emmenagogue in certain forms of amenorrhœa?" Of the nineteen cases reported, one was a pregnancy, three were cases of excessive menstruation; of the fifteen remaining cases, five were unsuccessful, leaving nearly sixty-five per cent. of successful cases. Of those where the remedy failed, in at least three of them—Cases IV., XII., and XVI.—there was evidently some organic disease of the menstrual apparatus; this reduces the cases of functional amenorrhœa to twelve, ten of which, over eighty per cent., were successfully treated. For no other single emmenagogue is so great a percentage of successes claimed. Indeed, no other remedy recommended for this condition, with the exception possibly of iron, is so far-reaching in its therapeutic effects, and none reach out in so many different directions to do the work, as do the salts of manganese. I therefore answer in the affirmative.

"2. To what forms is it applicable?" Only to functional amenorrhœa, as contrasted with that produced by organic morbid conditions of the genital organs. It certainly cannot supply a missing uterus or ovaries, nor has it

been yet proven to stimulate to normal growth those organs when in a rudimentary state, or when they have become atrophied from any cause. Nor is it claimed for the remedy that it can puncture an imperforate hymen, straighten out the canal of an anteflexed or retroflexed womb, dilate a pinhole os, channel out an atresia of the vagina or uterus, or exert a curative influence upon inflammatory conditions of any of the pelvic organs, or upon ovarian cystic degeneration.

It is in menstrual disorders caused by abnormal states of the blood and the sympathetic nervous system that we claim for it sovereign power. Under the former we find it of value in anæmia, chlorosis, plethora, and even phthisis; and while I have never prescribed it in such cases, I think, on account of its tonic and invigorating effect, we might reasonably hope for some benefit in amenorrhœa from cirrhosis, Bright's disease, etc.

In those cases in which there is a decrease of nervous excitability and activity, an atonic condition of the ganglionic nervous system from emotional causes, mental depression, overwork, indolence, and luxury, want of fresh air and exercise, and occasionally from constitutional disease, it is the remedy *par excellence*.

"3. Is it also remedial to certain forms of dysmenorrhœa, menorrhagia, and metrorrhagia?" It will be seen how well the remedy acted in Cases VI., XV., and XIX., which were functional metrorrhagia; and it was equally efficient in the cases of dysmenorrhœa mentioned.

"4. To which of its component elements is this action due?" and, "5. What is the nature of this action?" I do not believe its remedial effects, in the cases recited, due entirely or principally to either the manganese or the potassium, but rather to the oxygen contained in composition. Drs. Ringer and Murrell claim that it is due to the manganese, but other observers, prominent among whom is Dr. Fordyce Barker, have shown that the chlorate of potassium, an oxidizing agent, is nearly if not quite as effectual. Dr. Broadbent has shown the same thing in respect to the chloride of potassium. On the other hand, it is certainly not due to the potassium, because the permanganate of sodium and the binocide of manganese accomplish the same results. I am thoroughly in accord with Roberts Bartholow that oxygen is, in the main, the remedial factor. Look at its formula,  $\text{KMnO}_4$ , an unstable compound readily decomposing, evolving seven-eighths of its oxygen, particularly

in the presence of moderate warmth and an acid, both of which conditions we have present in the stomach; hydrochloric and lactic acids with an internal temperature, especially during digestion, of something over  $100^{\circ}$  F. It is well known that this oxygen in its nascent state contains much ozone. The permanganate of sodium ( $\text{NaMnO}_4$ ), the binoxide of manganese ( $\text{MnO}_2$ ), and chlorate of potassium ( $\text{KClO}_3$ ), all containing a large proportion of oxygen held in yielding bonds, and therefore used by chemists as active oxidizing agents, undergo the same character of decomposition in the stomach, yielding almost as great a proportion of ozonized oxygen. This agent has a tonic and invigorating effect upon the central and ganglionic nervous systems. It is mildly stimulant to the entire organism and promotive of activity of all functions, the sexual function included. It produces a feeling of exhilaration and well-being, promotes digestion and assimilation, and therefore conduces to constructive metamorphosis, both by improving the quality of the blood and toning up the nervous system, thus proving of benefit in anæmia and chlorosis. Even those who hold that manganese is the component element of importance in menstrual disorders, grant that permanganate of potassium acts somewhat quicker and more readily, and in smaller doses, than any of the other salts, an acknowledgment in favor of the oxygen theory, because, while the manganese remains the same in all of them, the permanganate contains the greater proportion of oxygen than the others and parts with it more readily.

It is objected that this property of the drug of so easily giving up its oxygen to organic matter, in the stomach as elsewhere, renders it practically useless. I am not sure but that this very property is an advantage, for the simple reason that while the oxygen is quickly liberated, the processes of oxidation are all slow, and the stomach has ample time to take up a large proportion of oxygen, which is rapidly diffused into the blood. Again, the salt is very soluble, and, as well as chlorate of potassium, is so diffusible that not a small quantity of it is taken up, as such, by the blood before deoxidation has been completed.

Now, on the other hand, I do not deny that a certain, though small amount of this action, is due to the manganese. It also is an agent favoring constructive metamorphosis, being of the same chemical group as iron, nickel, etc., all of which exercise more or less influence either upon the sexual centres or the

sexual organs themselves. The result of Case II. is significant in this connection.

"6. Does the permanganate of potassium, or manganese in any form, improve the blood condition in anæmia or chlorosis?" From what has just been said such seems clearly to be the case, and such is the consensus of opinion as the result of experience with other observers; Ringer and Murrell being the only ones I call to mind now who dissent from this opinion. They say "the permanganate not infrequently brings on the period without in any way improving the anæmia." True, but I believe this to be the case simply because menstruation, in the cases referred to, was brought on quickly and the remedy discontinued; whereas anæmia and chlorosis both require prolonged treatment. They argue, too, that the treatment cannot be of benefit in anæmia because it succeeds equally well in plethora. I ask, would either of these gentlemen deny a patient iron to assist in stopping a hemorrhage because it is a blood-making agent; or deny a patient calomel in bilious diarrhœa because it produces bilious evacuations?

"7. Is the binoxide of manganese an efficient therapeutic agent?" A question scarcely necessary to ask, so convincing are the evidences and reports that such is the case; and that it is almost, if not quite, as valuable as the permanganate in functional menstrual disorders.

"8. What are the best modes of administering the salts of manganese?" Kaolin, cerate of petroleum, cocoa-butter, and other excipients have been recommended as suitable bases for pills; but, besides the liability to explosion, slow decomposition, etc., I object to its being given in pill form because of its local irritant action when it is held at one point in the stomach, as must be the case in the excipients mentioned. They dissolve slowly, and set up so much irritation at the point of the stomach at which they happen to be located as to cause griping pains, nausea, etc. Compressed tablets are objectionable for the same reason. It will be seen from my cases that after trying several methods I finally resorted to giving it pulverized and in capsules, followed immediately by one or two tumblers of water, preferably not cold. If this is done, the gelatin-capsules dissolve off quickly, leaving the salt free, having nothing to confine it to a limited space, to disperse itself over a considerable portion of the stomach; and being pulverized, and followed by a large quantity of water, it is dissolved rapidly, and

not concentrated enough to produce any distress at all in the majority of cases. Few of my cases treated in this way had any trouble. If, however, this method should be followed by much pain, I do not see any objection to the temporary use of hyoscyamus or small doses of a denarcotized preparation of opium to establish a tolerance. The binoxide may be given in capsules, and occasions very little disturbance. Two grains of the permanganate three times a day, and 2 to 4 grains of the binoxide from three times a day to every four hours, is about the proper dose. It is only necessary to begin with the permanganate six or seven days before each period, but the binoxide may be continued throughout the entire month for several months. Its value might be greatly enhanced by using it in conjunction with other remedies appropriately selected, though the tendency seems to be to give it alone. It is best borne when given about an hour after meals.

Why do we have so many failures reported? Several causes are apparent. The remedy is often abandoned too early, either because the proper precautions have not been taken to prevent its bad effects upon the stomach, the patient refusing to take it long, or because having tried it through one period without success, it is left off and some more familiar agent or remedy resorted to. My convictions are that if its use was persevered in the number of failures would be largely reduced. Then too many, whether wittingly or not, are guilty of the same grave fault with which I charged myself in the beginning, that of making a routine practice of its administration, not exercising sufficient intelligence and care in choosing their cases. They disregard diagnosis, and make no discrimination whatever between functional menstrual disorders and those caused by organic changes or diseases; and then because they necessarily often fail, lay the burden of their own ignorance or indolence upon a remedy which deserves better treatment. Finally, the treatment is not a specific for menstrual disorders; but, while I do not pin my faith indissolubly to it, I must say with Thomas that "permanganate of potassium is the best emmenagogue yet discovered."

14 SOUTH CHERRY STREET, NASHVILLE, TENN.

## HYOSCINE AS A HYPNOTIC.

BY W. D. HAMAKER, M.D., MEADVILLE, PA.

IT may be of interest to publish the marked effect of hyoscine in the following case. The patient is a clergyman, 57 years old, who for several years, owing to intense mental application, has been troubled at times with insomnia, which has been worse in the spring and early summer after the hard winter's work, and before he takes his summer vacation. Very often for weeks at a time he has been unable to fall asleep until four or five o'clock in the morning, and then only for a short time.

Ordinary hypnotics have been unavailing in producing sleep, a grain of morphine at one time and *seventy* grains of chloral at another time having failed to do any good.

The insomnia was followed later by headaches and loss of appetite and general loss of tone.

Previous to the administration of hyoscine he had suffered for several weeks from most distressing insomnia, and violent headaches from the loss of sleep.

Knowing the ineffectiveness of the ordinary hypnotics, I prescribed a solution of hyoscine hydrobromate, containing  $\frac{1}{12}$  gr. to the teaspoonful. I give the patient's own account of its effects:

"June 14.—Sat in complete repose for an hour, reading. Respiration 18; pulse, sitting, 70; standing, 76. Pulse irregular, contracted, and very easily compressible. Pupils natural; no headache; no inclination to sleep.

"At 11.30 P.M. took  $\frac{1}{12}$  gr. hyoscine in solution.

"At 12.15 respirations 16; pulse, sitting, 67; standing, 72. Pupils *slightly* dilated; no interference with accommodation; no peculiar sensations or feelings noticeable. Fell asleep at 2.30 and slept till 8 A.M. Awoke refreshed; pupils natural; no headache.

"June 15.—Respirations 19, and pulse, sitting, 80.

"At 11.15 P.M. took  $\frac{1}{8}$  gr. hyoscine.

"At 12 M. respiration 16; pulse 70; pupils very slightly dilated. Fell asleep at 1 A.M.; slept till 7.30; no unpleasant effects; no headache; feel much better on account of refreshing sleep.

"June 16.—Respirations 18; pulse 82.

"At 11.30 P.M. took  $\frac{1}{8}$  gr. hyoscine.

"At 12.30 respiration 14; pulse 61. Pulse irregular and very feeble; pupils very slightly dilated; slept five and one-half hours.

"June 17.—Respirations 18; pulse 80.

"At 11.15 took  $\frac{1}{8}$  gr. hyoscine.

"At 12.15 respirations 15; pulse 70; slept six hours."

At another time the patient took  $\frac{1}{8}$  gr., when respirations fell to 13 and pulse to 58. Pulse became very irregular and weak.

The solution of hyoscine used had been made several months previously, and had been kept in the light. Attention was called to this, when the patient obtained a fresh solution of the same strength ( $\frac{1}{112}$  gr. to teaspoonful). He took one night two teaspoonfuls ( $\frac{1}{8}$  gr.), and in a short time respiration became very slow and the pulse fluttering, and finally scarcely perceptible.

After this the dose was maintained at  $\frac{1}{112}$  gr., and always had the desired effect. The question arose whether the solution of hyoscine deteriorates by long standing or by exposure to light.

In this case, then, the effect of hyoscine was,—

1. To affect respiration, reducing the number of respirations from three to six per minute in a short time. A source of error lies in the fact that the patient counted the respirations himself, but uniformly there was diminution.

2. To cause slowing of the pulse-rate at every administration, and to weaken the force of the pulse.

3. To produce or *allow* natural sleep. The sleep was always refreshing, and without any after-effects of the drug whatever.

4. To cause sleep, but not to cause "drowsiness" previous to the induction of sleep.

5. In overdose ( $\frac{1}{8}$  gr.) to produce alarming disturbance of the heart's action. At one time the patient feared absolute failure of the heart after taking  $\frac{1}{8}$  gr. of the new preparation.

6. Entire relief of headache which had been so distressing.

7. Improvement in general health, following, of course, the natural sleep obtained every night.

The patient continues at present to take  $\frac{1}{112}$  gr. at bedtime with happy effects. The benefit in this case was more noticeable on account of the utter failure of ordinary hypnotics.

A friend of mine, some weeks ago, prescribed  $\frac{1}{100}$  gr. hyoscine for a young lady suffering from phthisis. It produced violent delirium. Afterwards  $\frac{1}{200}$  gr. produced sleep, and was attended by no bad effects.

The dose of hyoscine, as indicated by these

two cases, should always be small at first, and gradually increased as it is required or is well borne. I remember to have given to a patient in the University Hospital  $\frac{1}{8}$  gr. hypodermically. He was suffering from delirium tremens, and his heart was very weak. He slept several hours, and showed no bad effects. This I should regard as a dangerous dose until smaller doses had been tried.

#### THE TOXIC EFFECTS OF TEA.

BY JAMES DAVIES, A.M., M.D., CANASERAGA,  
ALLEGANY CO., N. Y.

THE perusal of Dr. Thos. J. Mays's paper on "Tea and its Alkaloid, Theine," has induced me to ask of you space for a few remarks from the Druidic faculty, which, in my opinion, may set matters right between Dr. Mays and Drs. Bullard and Morton, or, at least, help to do so. The Druids have thoroughly investigated the subject of tea by the tests of experimental physiology as well as those of chemistry. I will be as brief as I can.

1. Theine and caffeine are not identical.

2. There is such a thing as chronic tea-poisoning, and, in the main, Dr. Bullard is right, as far as the reflections on the consumption of tea by the public are concerned.

3. Dr. Morton is perfectly right in concluding that the continued and immoderate use of tea led to headache, vertigo, ringing in the ears, tremulousness, nervousness, exhaustion of mind and body, with disinclination to mental and physical exertion, increased and irregular action of the heart, dyspepsia, diminution of the amount of urine and urea, and retardation of the metamorphosis of tissue.

4. These symptoms ensue from the use of the infusion of tea.

5. Sleeplessness should have been added to the list.

6. The consumption of three grains of theine per day, or even of five, would not cause the above symptoms.

7. The consumption of tea containing so much theine—that is, the partaking of it according to the usual manner of the common people—would tend to produce the aforesaid symptoms.

8. The great subject is the consumption of the infusion of tea-leaves, but Dr. Mays's subject is another thing altogether, namely, the administration of theine.

9. The tea-tasters, as well as our tea epicures, principally get hot water and theine from the infusion; but the public would consider that product a most unsatisfactory thing.

10. Tea contains boheic acid and tannin, as well as theine and an essential oil.

11. The common people must wait for the tannin to draw before the infusion is worth the drinking.

12. What are the physiological effects of tannin on the human stomach, and especially those resulting from the persistent use? I need not rehearse them to the medical readers of the GAZETTE; but I would ask them to compare them with above symptoms.

13. The physiological effects of tannin, as handed down to us by the Druidic College of the twelfth century, are identical, as far as they go, with those reported in our modern medical and pharmaceutical works; but I would add that the old Druids further considered tannin the most potent of all the products of nature in producing *sterility* and *barrenness*; and tea-drinking, as practised by the public, undoubtedly acts in the same direction.

#### RESORCIN IN ECZEMA.

By H. P. CHACE, M.D., HIGHLAND FALLS, N. Y.

I WISH to call the attention of your readers to the use of resorcin in eczema. In the April number of the GAZETTE I saw a report from Dr. Wyss, taken from the *Fortschritt*, of his use of this remedy. I had at that time upon my list two cases of general eczema that had defied the whole range of eczema remedies. One case was about six months' standing and the other four months'. Both persons had been subject to this disease for years, at times. One of my patients having had it several years ago continuously for fifteen months was seen by two New York City specialists, and finally went to Europe and consulted the famous Erasmus Wilson. I go into this detail to show that the case was of the obstinate type. The attack for which I was attending him had lasted about four months. The eruption extended over every part of his body, except from the knees down. The scrotum was swollen to three times its natural size; the face and eyes swollen very much, and, as may be imagined, the itching and burning was intolerable.

My other case was but a repetition of the one I have described, except that the erup-

tion completely covered the body at times, and would then get a little better in some places, but in a short time returning with renewed force.

After reading the article referred to, I immediately ordered from my druggist the following:

R Resorcin, ʒii;  
Glycerin, q.s. ʒii. M.

Sig.—Apply with camel's-hair pencil morning and evening.

I had very little faith that my patients would receive any benefit from it, but, to my great surprise, the remedy worked like magic. Improvement was marked in forty-eight hours, and in one week both of my patients were attending to business, and are both at this writing perfectly well. Since then I have had sent me one other case of general eczema, and six cases that were localized, the remedy proving just as efficacious in every instance except one. In one case the lady could not follow my directions about keeping her hands out of water. In this case the hands are very much better, but not yet entirely healed.

I see in a report from the Dermatological Society, Dr. Stelwagon, of Philadelphia, claims resorcin is rarely of benefit in this disease. I cannot help but feel that the doctor has not given it a thorough trial, and believe, if used properly, it will prove a blessing to both patient and physician.

#### A LIPOMA REMOVED BY ICHTHYOL.

By JOSEPH SCHMIDT, M.D., BERLIN, GERMANY.

IN connection with the papers on ichthyol appearing in the June and July issues of the THERAPEUTIC GAZETTE, I beg to communicate to the profession the therapeutic effects obtained with ichthyol in a case of lipoma.

The following embodies the salient points of the clinical history of the case:

Uso von Berg, a medical student from Dorpat, aged 26, presented himself for treatment for some trivial gastric disturbance. While treating this gentleman my attention was directed to an ungainly lipoma of the size of a pigeon's egg, situated on the left side of the neck over the carotid artery. Inquiry elicited that the patient had had this tumor for the last eight years, and that no signs of any change in its size had presented themselves. He also admitted that he was very anxious to

get rid of the unsightly swelling, and that he had in vain used applications of the so-called interstitial absorbents, such as iodine and mercury. The proximity of the tumor to the great artery had always been regarded, both by himself and by the physicians of Dorpat, as a sufficient cause to interdict any surgical interference with the neoplasm.

I asked the patient whether he had ever heard of ichthyol and of its unrivalled absorbing power. Ichthyol was used in Dorpat, he answered, in the treatment of eczema, but he had never heard that the drug possessed absorbing qualities. I then told the patient that I had seen veritably astounding results in more than thirty cases from the application of ichthyol in infiltrations of the cellular tissues or of joints, and that I would like to try the new remedy on his lipoma. The patient readily consented, though candidly admitting his incredulity regarding any curative results.

I applied the fifty per cent. solution of the ichthiosulphate of ammonium (obtained from Cordes, Hermann & Co., Hamburg) three times daily for ten successive days by thoroughly rubbing the drug into the part. As in all external applications of ichthyol, I washed the part previously with lukewarm soap-water, so as to open the pores of the epidermis and favor the absorption of the drug.

Sharing, as I did, the incredulity of my patient concerning the benefit to be derived from this novel treatment of a fatty tumor, the results obtained ultimately were naturally all the more surprising. On the first, second, and third days no alteration, either in size or consistency of the tumor, could be discovered, and physician and patient came wellnigh abandoning what appeared an utterly hopeless medication, when, on the fourth and fifth days, careful measurement and palpation revealed a distinct decrease in size and appreciable softening of the swelling. Stimulated by this promising improvement, the treatment was continued for six more days, each successive day marking a further decrease in size and a greater softening of the part. On the ninth day of the treatment the tumor had grown so soft that a fluctuation could be distinctly made out, and the size of the lipoma had so materially decreased that this fact was noted with surprise by friends of the patient wholly unaware of the treatment. On the same day a yellowish-white spot suddenly appeared on the top of the tumor, which rapidly expanded into a zone marked by great pliability and thinness. It was then clear to me that I stood before a singular pathological process: that

the thin yellow zone was evidently a suppuration focus, and that the drug had transformed a fatty tumor into a simple abscess about to open spontaneously.

I consequently withdrew the ichthyol applications, and treated the tumor as an ordinary abscess, *i.e.*, facilitated its impending spontaneous opening by the aid of the bistoury. My surprise, however, cannot be imagined when, scarcely having touched the part with the knife, a sero-purulent whitish mass gushed vehemently from the tumor, squirting over the room and clothing of both operator and patient. I then pressed the still remaining liquid with my fingers out of the abscess, extracted with the forceps the base and sides of the capsule of the former lipoma, and dressed the part with ichthyol adhesive plaster. On the twelfth day, after the plaster was removed, the part was found to have completely healed, and not the slightest trace of a swelling was left.

Shortly after the unique issue of the treatment of this case, I told Dr. Unna about it, who asked for the privilege to publish the case in his *Monatshefte für Dermatologie*.

In view of the above unprecedented result obtained with ichthyol in a case of lipoma, it would be very desirable to give the drug further trials in the direction indicated. The hope to cure by mere external medicinal applications what heretofore was only possible by the *ultimo ratio* of the knife, ought to prove a powerful stimulant for further trials.

#### USE OF BLACK HAW IN HABITUAL ABORTION AND OTHER UTERINE TROUBLES.

BY CHEVES BEVILL, M.D., WINFIELD, ARK.

IN 1878 my attention was called to the haw in a paper published in *New Remedies*, page 105, April, 1878. I first employed it in the case of a lady who had aborted three times. It was used from the third to the fifth month with her with good effect, and she went to full term, and since has borne two children without any inconvenience.

Besides this case I have employed the haw in sixteen cases of threatening abortion that I have notes of, besides seven others of which I have no record. Six of these patients had aborted from two to four times. In five of them the child was carried to full term. In one abortion occurred, but I do not think the drug was kept up long enough to have the desired effect.

Three of the sixteen had aborted once, and they all went to full term, and did well.

Of the remaining three cases noted of primiparæ two aborted, and I feel sure that too much time had been lost before they let it be known, and the membranes were broken.

In half of these cases I did not have the fluid extract of the haw, and had to make a decoction of the bark of the root, which I think is best. In giving the fluid extract I give from 30 to 60 drops from two to four hours apart, till all pains cease.

In congestive as well as obstructive dysmenorrhœa, I find it very beneficial, increasing the flow in the obstructive form,—i.e., obstruction from clots and shreds plugging up the canal.

In after-pains it has acted well with me, causing the patient to rest well.

By its quieting effect on the contracted uterus at the menstrual epoch, black haw allows the flow to go on without causing the patient to suffer as much as she would without it; and, if given in sufficient quantities, I believe it will prevent abortion in almost every case where the placenta is not detached or the membranes broken. It has never, in my hands, affected the stomach enough to produce nausea.

#### ANALGESICS.

At the meeting of the Section in Therapeutics of the British Medical Association, the debate on analgesics was introduced by DR. SPENDER, in a paper rather too long for such a purpose, but full of interest (*Medical Record*, September 4, 1886). After some introduction, he said we come to close quarters with pain in neuralgia, calculus in the ureter, gall-stones, gout, etc., and patients demand relief at all cost. In such cases opium, or its alkaloid, still remained our chief agent. In supra-orbital pain, however, it was of little use, while 10 grains of quinine, followed by a few doses of 5 grains, would cure. Gelsemium or chloral were not to be compared in these cases, especially when, as usually, there is a touch of malaria present. Again, in night-pain in a syphilitic patient, analgesics of such a kind give only temporary relief, while iodides will, after a few doses, permanently remove the suffering. So salicin and arsenic are relatively indirect analgesics in other cases. Iron, in myalgia and neuralgia, has a similar relative value. Bromides only dispose to sleep, and in slight pain appear analgesic; but if the pain is sharp enough to baffle sleep, it defies bromides. They bring

the system into a placid state disposing to sleep, but if this is disturbed the analgesic charm is broken. He referred to doses, and illustrated the subject by the different effect in various quantities of tartar emetic, of opium, and morphine. Bleeding relieved vascular tension. Ergot raised motor force, and possibly sensation. He next urged that we economize our power by combining drugs, instancing morphine given with bromides, aconite with quinine, hemlock with several others, quinine with arsenic in herpes zoster, or with colchicum in gout, etc. He thought that, as surgeons have their instruments all in place, so as to find just what they want, so physicians should have a cupboard where all their analgesics could be seen in order at a glance, with hypodermic syringes and other means of employing them. He concluded with a recognition of physical analgesics, and the importance of recognizing not only the mental influence which by the sight of the dentist dismisses toothache, but the spiritual comfort which the presence of a wise, Christian physician may insensibly impart.

The PRESIDENT thanked Dr. Spender, and asked Dr. Brown-Séquard to follow.

DR. BROWN-SÉQUARD then gave an account of his discovery that a jet of carbonic acid gas, or of the vapor of chloroform, projected forcibly on the larynx, produced anæsthesia. Other agents will do it, but these are the best. After the larynx is thus anæsthetized the influence extends to other parts, and he has rendered animals insensitive to pain all over by this method. The effect lasts a long time,—twenty-four or even thirty-six hours,—and that without the least effect on consciousness or interference with any other function. He considered it due to an effect on the superior laryngeal nerve. When this nerve was divided, on one side there was no anæsthesia at all. He divided both and scarcely any effect occurred on either,—only just enough to be attributed to the other less important nerves.

The higher the scale of the animal, the greater the effect. He had tried to apply it to man and had succeeded on himself, but the effect of projecting CO<sub>2</sub> on the laryngeal membrane is so exceedingly disagreeable, he had found no one else able to endure it for a long enough time, and, of course, precautions must be taken to prevent its inhalation. He was still, therefore, searching for an agent suitable for use on mankind. Galvanism of the nerve sometimes acted in the same way, but was very uncertain, and therefore useless.

### REFLECTIONS ON THE PROPER USE OF INSANE ASYLUMS.

THE asylum with its various appurtenances for the treatment and protection of the insane is one of the greatest boons which modern scientific humanitarianism has conferred upon a suffering race. It is, however, possible for even a great gift to be abused through misunderstanding. We have sometimes thought that the asylum has become in the minds of many practitioners of medicine a sort of fetish, a mysterious something which has peculiar and inexplicable effects upon disordered intellects, so that any insane person who has not had the opportunity of shelter and treatment within the asylum, has, in the estimation of the physician, been deprived of his rights. On the other hand, among many of the laity, a sort of stigma attaches to the insane asylum, so that when a person is sent to an institution a sense of disgrace is felt by the whole family. This is, of course, utterly wrong, although it rests upon a very natural feeling. Insanity is such a dreadful thing and is so strongly hereditary, that every person shudders at the thought of its being in his or her family. The sending of a person to an

asylum is a public admission of insanity, which involves to some extent not only the unfortunate individual but also the immediate relatives and descendants. It may even interfere with the life prospects of the young of either sex, hindering the one in the obtaining of responsible positions, the other in the securing of marriage. Further, the going to an asylum often involves an increase of mental suffering, especially when the insanity takes the form of a mild melancholia. Whilst, therefore, the superintendents of asylums often complain that patients are sent to them too late, it seems to us that it is possible to err on the other side, and to send patients unnecessarily to an institution. This is especially true when there are abundant pecuniary means at hand.

Insane asylums are chiefly useful as a means of saving expense. Very few remedial measures are instituted within an institution which cannot be as well carried out away from the asylums. A raving maniac can be controlled as thoroughly in a private house as in the wards of an asylum. A melancholic can be diverted and soothed as readily in a country mansion as in a country madhouse. Very frequently it is essential for the insane person to be removed from his old surroundings and to be put under new influences, but such new surroundings and new influences can be readily found away from asylums. There are cases, it is true, in which the discipline of the institution seems to have an effect, the disordered intellect yielding to the influence of numbers about him, but even this influence can be obtained in small private retreats. The asylums exist, and are justified because by their means insane patients can be treated at a comparatively small cost. In various of our recent exchanges we have read articles claiming that the insane could be treated at their homes, and so written as to give the impression that their authors thought they had made a discovery!

When there is the power of obtaining first-class medical care, abundant nursing, isolation, and proper hygienic surroundings, in the majority of instances we believe that even better results can be obtained outside than inside of an institute, but no physician ought to undertake the treatment of a severe case of insanity unless he is thoroughly assured that the necessities can be commanded.

In the case of the chronically or hopelessly insane, the question as to the use or non-use of the asylum frequently requires very careful consideration. The sane as well as the insane have rights, and a mild lunatic in a

family may make the existence of a large number of persons so miserable that souls in purgatory would not change places with them. Under such circumstances, unless the afflicted individual has enough means to take care of himself away from his family, or rather to be taken care of away from his family, he should be sent to the asylum. Again, there is a class of monomaniacs, or partially insane persons, who simply cannot be controlled unless in confinement, or unless legal authority be given some one to enforce obedience. It is these cases especially which come into court, and are not rarely let loose upon themselves and upon a much-suffering community. We never heard of such a thing being done, but we cannot see why, in such cases, power could not be given to a suitable person to take charge of the half-insane individual, and by means of attendants control all his acts. Probably an alteration of the laws would be necessary in order to give the court such power, except in the case of those lunatics who have committed some crime. According to our understanding of the law of Pennsylvania a court may, in the case of a person acquitted of a crime on the ground of insanity, release him, after a longer or shorter sojourn in an asylum, upon bonds for good conduct given by some relative, and we suppose the person who gives bonds has authority over the one who is bonded.

#### THE DIURETIC ACTION OF MERCURY.

IN several of our previous issues we have referred to the interesting results obtained by Jendrassik and Stiller through the employment of calomel as a diuretic in cases of heart-disease. These authors, however, have been unable to explain the manner in which mercury produces its diuretic effect, but, as pointed out by Mr. F. S. Locke in the *Practitioner*, September, 1886, the recent work of Noel-Paton on the connection between bile-secretion and the formation of urea seems to have furnished the required clue. Noel-Paton has found that there is a direct relation between the activity of drugs as hepatic stimulants and their activity in causing increased formation and secretion of the most important nitrogenous waste products. Drugs, therefore, which cause an increased formation of bile also give an increased formation of urea, and give support to the fact generally held by physiologists, that the liver is the great seat of the formation of urea. Rutherford has proved that mercuric salts cause an increased produc-

tion of urea through the destruction of the red blood-corpuscles. As is well known, an increased quantity of urea in the blood acts as a powerful diuretic, and we there have a plausible explanation as to the manner in which calomel acts as a diuretic. If we acknowledge the fact that calomel is a hepatic stimulant, which, by the way, is denied by Rutherford, and can believe that all hepatic stimuli are increasers in the production of urea, we have thus the chain of argument completed as to the way in which calomel may be of use in heart-disease. The evident break in this train of argument is the contradiction as to the action of calomel on the liver. Mr. Locke, who agrees with the statement of Rutherford as to the fact that calomel is not a hepatic stimulant, thinks that the specimens used by Jendrassik and Stiller contained a trace of the per-salt, or that calomel is to a slight extent decomposed in the alimentary canal, the formation of the per-salt thus being suggested in order to explain the great cholagogue effect of the drug.

#### FURTHER NOTES ON THE YELLOWSTONE REGION.

IN the editorial which we published last month concerning the possibilities of the Northwest as a sanitarium, we recommended that a chemist be appointed by the United States Geological Survey to make a thorough chemical study of the waters of the Yellowstone Park. In our recent visit to the Yellowstone Park we found no chemist present, and took it for granted that this portion of the work had been overlooked, but we are informed that Professor Gooch was for a long while stationed in the Park with a proper chemical outfit, and that afterwards he supplemented his work on the ground by studies of residuums at Washington. As the thermal springs of the Yellowstone are to be numbered by the thousands, an absolutely complete analysis of them is almost impossible, but it is stated that the work of Prof. Gooch has been very wide-spread. The reputation of the professor guarantees that the analyses, so far as they go, are thorough and reliable, and we look forward with much expectation to the forthcoming volume.

The law does not permit the opening of new boarding-houses, or even the location of private dwellings within the Park, except under a special agreement with the government, and at present there is much complaint

that a large stock company has practically a monopoly of the keeping of hotels and the furnishing of transportation in the Park. Without the granting of peculiar rights, it is not probable that any individual or corporation would have undertaken the task of developing the resources of the Park or of properly providing for visitors, but when such rights have been given, the United States officials should certainly see that proper sanitarian and other arrangements are made for the reception and treatment of the sick at reasonable rates. Only the rich can afford the prices at present charged in the Park hotels, but the people of the United States will finally assert their rights to the curative powers of this great thermal region.

#### UNNA'S PLASTER MULLS.

THE name of Unna has within the last five years or so become familiar not only to those engaged particularly in dermatological practice, but also to the general practitioner. The readers of the GAZETTE are aware that the profession owes quite a number of important therapeutic innovations to Unna. Among these we mention the keratinized pill, the knowledge of the medicinal virtues of ichthyol, the paste pencils, the oily medicinal soaps, and last but not least the medicated mulls. The name of plaster mull has been given to a dressing consisting of a very thin sheet of gutta-percha, coated on one side with an adhesive substance containing one or more medicinal compounds, and backed on the other side with mull or undressed muslin. The name of salve mull also has been given to a similar kind of dressing, in which the medicaments are of a more soothing character, consisting of ointments having a basis of suet and lard, spread upon mull.

The local application of strong salicylic acid "plaster mulls" is strongly recommended by Unna in the treatment of lupus. In experimenting with a strong salicylic acid plaster mull to remove the cuticle and prepare lupoid tissue for other more destructive agents, Dr. Unna observed that salicylic acid itself exercises a most beneficial influence upon the new growth. The chief drawback is the great and lasting pain caused by salicylic acid when applied to a thin epidermis or raw surface. In order to overcome this various combinations were tried; cocaine failed to give relief, while opium and cannabis indica required an hour or two to develop their anodyne effects. The best results were obtained when genuine

beechwood creasote was combined with salicylic acid in the proportion of two parts of creasote to one of acid. Even then there is a painful stage lasting from ten to fifteen minutes, but a previous application of cocaine is sufficiently lasting in its effects to cover this period. The salicylic acid plaster mulls used by Dr. Unna were of five different strengths, containing respectively 10, 20, 30, 40, and 50 grammes of salicylic acid, and 20, 30, 40, and 50 grammes of creasote to each strip.

#### FAIR PLAY.

IN an exchange which has hitherto had the reputation of being a respectable journal, we notice a bitter editorial attack upon the journals whose publishers are in any way connected with drug houses. It is intimated that such journals are run for the purpose of bolstering up certain preparations, and are therefore unworthy of support from the profession. We have doubted somewhat the propriety of noticing such attacks as these, but as the THERAPEUTIC GAZETTE is the most prominent of such journals printed in the English language, and as the unwary may occasionally be misled, a few words are allowable.

The competition in medical journalism in the United States is so great that there is very little money to be made out of it. Indeed, we believe that most of the American journals either do not pay their editors at all, or pay them very insufficiently for the labor, or else are published at an actual loss. When a medical man is proprietor and editor of a journal, he takes what he gets out of it, and if a few hundred dollars results from his year's labor, claims that his journal is on a paying basis. A publishing house, if it desire the services of successful physicians as editors, must pay commensurate salaries, and thereby increase the expenses of the journal. Each of the large medical publishing houses in the United States has its own journal, which is of value to it partly as a direct method of advertisement, but more largely for its indirect influence. To be known as the publisher of a widely-circulated journal is to have a direct road to the notice of the medical profession. It is just as allowable for those who provide drugs as for those who provide books to open such a medium of communication with the profession. The advertisement columns of American medical journals are commonly under the control of the publisher of the journal. The book purveyor uses these columns for his

books, the drug purveyor for his drugs. The text of a journal is under the control of the editors, and whoever the publisher of the journal may be, the character of the text depends upon the ability and the independence of the editors. False book notices may appear in the columns of one journal, just as false accounts of preparations or drugs may be published in another journal. The reader ought to judge a medical periodical partly by the known character of its editors, but more largely by the results of his own perusal of its contents. It is especially in the latter way that the editors of the THERAPEUTIC GAZETTE desire its readers to judge of it. If a review of its columns since it came under the present management shows that these columns are free from articles especially devoted to the interests of its publishers, and are open and fair-minded in their criticisms and in their praises, then those journals whose failing circulation and general feebleness betray them into the bad habit of deriding their more successful rivals ought to be eschewed. The editors of this journal believe they have at times acted even unfairly in excluding articles whose bearing might be misrepresented, and have always in this been upheld by the publisher. The charlatanism and effrontery of the attack which we have just noticed is well shown by the following extract from the editorial in question, in which others are upbraided for praising their own wares, and a whining plea made for patronage, in asserting "the remedy consists in buying books from firms which make publishing their only business, and who are above the suspicion of catering to the interests of any advertising dodge."

#### ON TELEOTHERAPEUTICS.

THERE is no reason why in this age of the telegraph, the telephone, and the telescope, our old and venerable therapeutical science should not conform to the leading spirit of the day, and introduce a perfectly seasonable teleotherapeutical departure. We have all the respect in the world for the savants constituting the "Congrès de l'Association française pour l'Avancement des Sciences," but we cannot say anything else than "credat Judæus Apella" to the paper read by Drs. Burot and Bourrie at the recent meeting of the Congress in Grenoble (*vide Archives de Pharmacie*, September 5, 1886). The statements of these gentlemen concerning the effects of drugs upon hypnotized per-

sons clearly exceed the limits of faith of even the most liberal medical editor. Burot and Bourrie affirm in their paper that sick persons in the state of hypnotism become very impressionable to the action of many substances, especially of medicines, so that these will produce their characteristic effects by only placing them in well-stoppered bottles within a certain distance of the patients.

These statements met with a good deal of incredulity (no wonder), and Dr. Luys was requested to examine the subject and report upon it. Strangely enough, Luys fully confirmed the observations of the two first-named gentlemen. Luys said he could produce nausea and vomiting by simply placing a sealed tube containing one or two grammes of powdered ipecac, without any previous notice, behind the neck of the hypnotized person. The effects produced, which include convulsions, paralysis, hallucinations, etc., are said not only to vary with the substance, but with the point of contact, so that certain substances will produce different emotional expressions, according as they are placed on the left or right side of the patient. M. Luys concludes that medical men have thus placed within their reach a new method of treatment in nervous disorders, and he states that in this way he has obtained a distinct diminution of convulsive attacks in two patients suffering from hysteroleptic convulsions.

We are desirous of hearing more of this interesting subject. Possibly we may become converts yet.

#### Reports on Therapeutic Progress.

---

##### THE USE OF RESORCIN IN GASTRIC AND CUTANEOUS DISORDERS.

At the recent meeting of the British Medical Association in Brighton, DR. EDWARD MACKEY read a paper with the above title in the Section in Therapeutics. (*Medical Record*, September 4, 1886.)

He drew attention first to its antiseptic properties, pointing out that a two per cent. solution retards putrefaction, but does not irritate the tissues. Sometimes a five per cent. or even a ten per cent. solution may be employed, but then considerable irritation may be excited, while the weaker lotions are generally effectual. Internally he had usually employed 5-grain doses. It is not nasty, but the taste is easily tolerated by almost all patients. He usually gave it in water, with a

little glycerin, or in chloroform water ; doses of 20 or 30 grains have been given, but they give rise to febrile disturbance, while from 30 to 60 grains cause giddiness, prostration, anxiety, collapse, and unconsciousness. He therefore did not approve such doses. It was quite true that full doses lower the temperature, but the effect is only temporary and of doubtful advantage, so that resorcin may be said now to have passed out of the list of antipyretics. Two cases of gastric ulcer, treated in the County Hospital, with 5-grain doses three times a day, began to improve as soon as the resorcin was taken, and completely recovered under the treatment. In one of these anæmia was so extreme that he had resorted to hypodermic injection of dialyzed iron, as employed by Da Costa. Twelve cases of gastric catarrh among the out-patients of the hospital, varying in age from twenty-seven to fifty, all of whom had been vainly treated by bismuth, magnesia, soda, prussic acid, and the usual prescriptions, soon got better under 5-grain doses of resorcin *ter die*. The drugs seem to stimulate and disinfect the mucous membrane. In children's diseases he had not found it so successful ; he had given it in doses of 2 and 3 grains in children, but found that it neither relieved diarrhoea nor disinfected the evacuations. In skin-diseases it was a valuable parasiticide ; a ten per cent. solution sometimes relieved psoriasis. On ulcerating mucous surfaces it improved the condition and disinfected the discharge, as, for example, in otorrhœa.

MR. WILBERFORCE SMITH said that it seemed to act like carbolic acid, and he would like to ask whether the author had separated the effect from that of physiological treatment, which was often so effectual ?

DR. MACKEY replied that he had already pointed out in the paper the differences between resorcin and carbolic acid, the most important being that it was decidedly less irritant. As to physiological treatment, of course his two in-patients had the benefit of rest, proper diet, and hospital care ; but among the out-patients there was little opportunity for securing such benefit, and all that could be done in such cases was to give physic, as the patients could not, as a rule, comply with other directions.

#### GINSENG.

Ginseng is a drug about which not a little has been written, but concerning which not much is known, at any rate not sufficient to

explain the high estimation in which it is held by the Chinese. Another contribution to its literature has recently been made by Mr. FOULK, United States consul to the Corea, from which country the most valued varieties are derived. Mr. Foulk says that the plant is cultivated in the Corea, and that the ginseng is of two kinds, the red ginseng (heng-lum) and white ginseng (pak-lum). Both kinds, however, are from the same plant, the white ginseng being the root simply washed and dried, and the red the root after having been submitted to a process of curing. This process consists in prolonged steaming and dyeing, cold water being dashed over it at the end of the operation, which solidifies the root, the fracture becoming glossy and brittle, while its color is changed to a fleshy pink. The curing is a monopoly of the government, red ginseng not being an article of ordinary trade, but the whole of the crop being carried to China, and the proceeds of sales going to the king ! White ginseng is used enormously in the Corea as a strengthening and blood-purifying medicine, the natives preferring it to the red, which, they say, loses strength in the curing. The most esteemed ginseng should consist of the roots of wild plants at least thirty years old, and commands fabulous prices. Mr. Foulk says that from personal experience and observation he is satisfied that ginseng is an active strongly heating medicine, but caution is required in its use, as it sometimes causes boils and eruptions, sleeplessness, and flushing of the body. It is most commonly taken in the form of a concentrated infusion, but sometimes the sliced fresh root is eaten with honey. Notwithstanding the general impression among Western nations that the virtues attributed to this drug are imaginary, Mr. Foulk thinks the evidence is in favor of the mystic value having been attached to it after its virtues had been practically ascertained. Some yellowish specimens that are met with occasionally appear to be imperfectly cured red ginseng.—*Pharm. Journ. and Trans.*, August 28, 1886.

#### THE TREATMENT OF SUMMER DIARRHŒA OF INFANTS.

In the summer diarrhœa of infants, the fever, when present in considerable degree, is by long odds the most dangerous symptom, and this DR. H. C. HAVEN (*Arch. of Pediatr.*, July, 1886) believes to be best overcome by cold water applied by stripping the infant, laying it upon the blanket, and covering with

a sheet wrung out first in water of say 95° F., and changing the sheet every five minutes with one in which the water is gradually reduced to about 60° F. This application relieves the irritability of the nervous system; it supplies through the skin the water that has been lost from the intestines, and thus relieves the heart. It causes derivation to the skin, which can be intensified by the addition of rubefacients; this again relieves the heart and internal organs by restoring the equilibrium of the circulation. It spares the stomach and intestines from the additional irritation of an antipyretic drug. Antipyrin hypodermically or by the mouth may prove its equal; it is certainly the best substitute we have at present.

In the early stages, or even the approach of the state of collapse, opium is a most important adjunct to treatment. The bromides will often take its place, but their action is slower and possibly more depressing in the end. The study of the pulse and auscultation of the heart are necessary in addition to determine as to the time and amount of the use of alcohol and of digitalis, and other cardiac tonics and stimulants. Digitalis is a drug which, if employed rationally, is of great value, not only in this but in all diseases of infancy accompanied by a cardiac weakness. Nutrition must also be kept up if possible on account of its influence on the general condition. It must not be forgotten that food may be the initial irritant, either from changes which have occurred in it previous to digestion, as acid fermentation and putrefactive change, or subsequent to ingestion, as further fermentation, incomplete digestion, etc. Milk is the usual food of such infants, and Dr. Haven believes that the fermentative changes in the milk, which is a fluid undergoing such changes with the greatest rapidity, are the most important etiological factors; as a consequence, the first step in the treatment of this affection is to withhold milk entirely for a longer or shorter period. Its place may be taken by sugar in simple solution, white of eggs in solution in water or fresh beef juice, or the two latter combined; barley water may furnish the necessary sugar, or one or the other of the different malt foods may be employed. Fat can be dispensed with, or may be given by inunction, or, later, in almost infinitesimal doses of some sweet emulsion of cod-liver oil. The use of an alkali is further an important point in the treatment of all severe cases characterized by an acid condition of the intestinal tract. Of alkalies, Dr.

Haven prefers the sodium salts, especially the benzoate or the bromide, if there is irritability of the nervous system, or the salicylate may be used for its anti-fermentative properties. The use of the latter salt has been especially recommended in this affection by Dr. A. Shank in the same number of the above journal.

#### THE TREATMENT OF SYPHILIS BY SUBCUTANEOUS INJECTIONS OF MERCURY.

MR. J. ASTLEY BLOXAM (*Lancet*, August 21, 1886) recently delivered a lecture on the excellent results which he had obtained at the Lock Hospital and elsewhere in the treatment of syphilis by intra-muscular injections of a solution of the perchloride of mercury. The solution for injection contains six grains of the perchloride to the ounce of distilled water, and should be made fresh for each *stance*. Since he had adopted this method, now a period of some eighteen months, upwards of fifteen hundred cases had been treated with the best results. The sore generally begins to heal very promptly after one or two injections, the secondary symptoms are markedly modified, and, after a course of treatment extending over a year, more or less, the patient is enabled to discontinue his attendance. Towards the latter end of the course of treatment the injections may be given less frequently, and, as a general rule, not more than from eight to twelve grains of the perchloride are injected in all. It is undesirable to repeat the injections oftener than once a week, as otherwise salivation might be induced, and the quantity injected each time (one-third of a grain) is found to be quite sufficient until the next time. There are several advantages attending this method of exhibiting mercury. In the first instance, it is only necessary to see the patient once a week, when sufficient mercury is injected to last until the following week; secondly, salivation is not produced, as when the patient continued to take mercury for a whole week away from the supervision of his medical attendant; thirdly, the gastric derangements which are so apt to follow the administration of mercury by the mouth are by this means avoided; lastly, the ease and certainty of the administration, which enable the surgeon to do his own dispensing with a minimum of trouble. A little quinine is generally given during the course as a tonic, but no other form of mercury is administered.

The injection itself is a very simple opera-

tion, but certain rules have nevertheless to be observed in order to obviate any inconveniences which might otherwise result. An ordinary glass hypodermic syringe is used with a fine needle (the needle is apt to become very brittle from the action of the mercury on the steel, and requires to be replaced from time to time), containing twenty drops of the solution, equivalent to one-third of a grain of the perchloride. After filling the syringe, the needle is freed from adhering solutions by washing in order to avoid irritation in its track, and is then plunged deliberately into the muscular tissue of the buttock, selecting for this purpose the spot corresponding to the muscular mass of the glutei into the substance of which the injection is made. If this precaution be observed, no discomfort or abscess formation follows, the only solitary case in which this has occurred being attributable to the injection having been made into the areolar tissue over the trochanter. The pain of the injection is but slight, and soon passes off. It is desirable that the patient should not take active exercise immediately after the injection, as it has been noticed that blood may be effused at the point of injection, giving rise to the sensation of a severe bruise of the part, which lasts for several days. The same effect has followed the puncture of a large vessel, but in any case the result is only transient, and disappears after the lapse of a few days. If for any reason the buttock be objected to as the site of the operation, the injection may be made into the trapezius muscle at a point two inches above the superior angle of the scapula, but the injection into the buttock is attended with less inconvenience.

Mr. Bloxam mentioned that his own opinions were strongly in favor of syphilis being bacillar in origin, thus accounting for the specific action of mercury in the treatment of the disease. In support of this view, he alluded to the remarkable researches of Messrs. Eve and Lingard, whom he had furnished with blood and chancrous tissue from patients at the Lock Hospital, the subjects of syphilis.

#### THE NIGHT-SWEATS OF PHTHISIS TREATED BY SECALE CORNUTUM.

MINGOT reports in the *Journal de Médecine de Paris* (July 4, 1886) as to the unexpectedly favorable results obtained with secale cornutum in the night-sweats of phthisical subjects. He observed in Tenneson's clinics at Paris that 15½ to 31 grains of ergot given in powder

form, or, better, 2 fl. dr. of ergotinine injected hypodermically half an hour previous to the expected appearance of the sweat, could suppress the latter for a week or even longer. No other of the numerous remedies recommended against night-sweats was, save atropine, found to have so great an effect as ergot or ergotinine. To be sure, the tubercular process is in no way influenced by the exhibition of this remedy, but it is gratifying to be able to stay one of the most annoying, and at the same time weakening, factors of the disease.

#### SOME NEW USES OF SOME OLD DRUGS

DR. JOHN H. JONES (*New York Med. Journal*, August 21, 1886) recommends the following uses of some old-time remedies which have proved very effectual in his hands :

I. *The inhalation of ether in non-expansion of lung*, due to adhesions of pleural surfaces, occurring after pleurisy with purulent effusion, in apneumotosis of children, and asphyxia neonatorum.

After absorption or artificial evacuation, we frequently find that a long-continued effusion in the pleural sac is followed by destructive changes in the corresponding lung. Many remedies have been tried with the object of expanding the air-vesicles and preventing the occurrence of carnification, but with unfavorable results. The most effectual treatment heretofore has been that of breathing compressed or rarefied air. But by far the best method, in Dr. Jones's experience, is inhalation of ether. He has used it on three patients with very flattering results, and can confidently recommend it to the profession as the best means of dilating the air-vesicles and restoring the lung to its natural state. If the adhesions have not been of too long standing and are not very dense in structure, they will certainly yield, and, once overcome, will be permanently obliterated. A careful mapping out of the area of dulness should be made prior to administering the anæsthetic, and, if it is found that it is not appreciably diminished after two or three administrations, it will be an indication that re-expansion is hopeless. Often, however, one administration will suffice. It is undesirable to push the anæsthetic to complete narcosis. It should be discontinued after the stage of excitement has been reached.

Its inhalation is sometimes serviceable in the capillary bronchitis of children, when we suspect that one or more of the smaller bronchi

have become impervious. It is true that counter-irritation to the affected area and emetics are frequently successful in overcoming the obstruction; but, when asphyxia seems to be progressive and is accompanied by asthenia, emetics are too depressing, and their action cannot be relied upon. Under its use the heart's contractions are strengthened, and a violent anti-respiratory (forced expiratory) action is set up, which frequently is sufficiently powerful to dislodge the offending secretion.

Dr. Jones also recommends the use of ether in the asphyxia of newly-born infants. It will sometimes succeed when artificial respiration fails. A few drops may be placed upon a piece of absorbent cotton and held to the nostrils. A better method is, after the nares have been cleansed of mucus, etc., to insinuate into either nostril a camel's-hair brush previously dipped in ether, and, by titillating its mucous membrane, we, in addition, summon to our assistance the benefit of reflex action.

## II. *Bichloride of mercury and tincture of belladonna in membranous croup.*

Dr. Jones has for some years been in the habit of treating this disease with a combination of corrosive sublimate and belladonna. These drugs are recommended for this complaint in almost every work on therapeutics; but he believes that they have never been given conjointly. He has found that small doses of the bichloride ( $\frac{1}{10}$  of a grain), administered in conjunction with tincture of belladonna (2 to 5 minims), every half-hour, for a child 2 years old, is a very successful method of dealing with this dangerous disease of childhood. The secret of its success is in its persistent administration, even when the symptoms are apparently most unfavorable. It is advisable to commence the treatment by administering an emetic, so as to dislodge the already-formed membrane. Probably much of the benefit derived from this mixed treatment is due to belladonna, and it is astonishing what large doses of this drug children can tolerate. During the progress of the disease the strength must be maintained by a liberally nutritious diet and stimulants, for when recovery takes place, the patient is left very anæmic and weak. This is not very apparent while the medicine is being given, as every evidence of it is partially masked by the physiological effects of the belladonna.

## III. *Belladonna in sterility of females.*

There are few drugs which exhibit so pronounced a predilection to act upon certain

structures of the body as belladonna. Among its favorite tissues, those of the female sexual organs may be mentioned. Its employment is followed by more or less benefit in every disease to which these parts are liable. Apparently many sterile women enjoy the best of health, and have never suffered from any irregularity of the sexual apparatus. To such he has on several occasions prescribed belladonna internally, and has found that, after taking the medicine for some weeks, they became pregnant.

## ON THE PHYSIOLOGICAL AND THERAPEUTIC ACTION OF ETHOXY-CAFFEINE.

In a previous issue our readers found a review of the results and conclusions arrived at by Drs. Dujardin-Beaumetz and his pupil Pineau concerning ethoxycaine (*vide Bulletin de Thérap.*, March 30, 1886). In a recent issue of that journal (September 15, 1886), DR. CHABOT publishes another paper on the physiological and therapeutic action of the drug, which is worthy of our attention.

Ethoxycaine belongs to a series of derivatives of caffeine, which were prepared by Fischer, and examined as to their physiological properties by Filehne, of Erlangen. This observer showed that the physiological properties of the caffeine derivatives (hydroxycaine, diethoxy-hydroxycaine) were modified in proportion to their atomic formula, and that their degree of activity is greatly inferior to that of caffeine. The study of these bodies may be interesting enough from a chemical and physiological point of view, but the therapeutical science can, it seems, profit but little from them. Ethoxycaine, however, although nearly the counterpart of caffeine as to physiological action, presents, nevertheless, certain new and important features, insuring for the drug *a priori* a certain rank in our pharmacal treasures. The drug is undoubtedly a hypnotic. The experiments of Filehne have first established this fact, and the later researches of Chabot confirmed it. Ethoxycaine acts in the first place on the nervous centres (somnolence, augmentation, diminution of reflexes), then causes paralysis, and finally muscular rigidity. The circulation remains nearly unaltered.

From his researches Filehne draws the conclusion that "if you add to caffeine the group ethoxyl ( $\text{OC}_2\text{H}_5$ ), the affinity of this chemical becomes greater for the central nervous system, and weaker for the muscular system."

Chabot has taken especial pains to verify this interesting observation.

Knowing that on injecting into a muscle a solution of caffeine the former assumes very rapidly a state of rigidity, Chabot injected successively into the muscles of the thigh of several rabbits solutions of caffeine, of ethoxycaine, and of salicylate of sodium. The experimenter examined in especial the action of the last-named substance, so as to avoid all sources of error. The following was the formula for the solutions employed :

R Salicylate of sodium, 0.25 ;  
Caffeine, 20 ;  
Distilled water, 3 c.c.

The injection into the muscles was performed with 4 drops of these solutions.

These experiments yielded the following results: The muscles became rigid in two to three minutes when caffeine was used, and in eleven to sixteen minutes when ethoxycaine was used. If the latter drug is used, the muscular rigidity is accompanied and preceded by certain general characteristic symptoms. The lively disposition of the animals subjected to the action of caffeine contrasts most conspicuously with that of the animals treated with ethoxycaine; in the latter animals the rigidity is preceded by paralysis.

Another fact established in these experiments by Chabot is also noteworthy. When the animals were treated with ethoxycaine the respiration slackened progressively at the end of three to ten minutes, while caffeine produces nothing like that. Of course there is nothing remarkable in the fact that a substance like ethoxycaine, which acts so energetically on the central nervous system, modifies also the vitality of the respiratory centre.

Filehne terminated his valuable paper by saying that the sedative and hypnotic action of ethoxycaine allowed us to hope that the drug would be of value in the treatment of megrim, especially in the cases treated previously with caffeine with some success. Dujardin-Beaumetz administered ethoxycaine to six patients. The drug, insoluble in water, was given in doses varying 0.25 to 1 gm. The following is the routine formula of the French therapist :

R Ethoxycaine, 0.25 ;  
Salicylate of sodium, 0.25 ;  
Hydrochlorate of cocaine, 0.10 ;  
Linden-water (eau de tilleul), 60.00 ;  
Syr. capillaire, 20.00.

The cocaine was introduced into this for-

mula in order to counteract the stomachic pains which ethoxycaine occasionally produces.

In the first case, that of a man aged 52 years, suffering from a very painful zone, 1 gm. of the drug was given in five doses at half-hourly intervals, with the result of producing sleep, which the preceding injections of morphine were unable to procure.

The second case was a nervous and anæmic woman, suffering from an almost continuous cephalalgia, combined with insomnia. She took 50 cg. in five doses. The last doses produced some nausea and vomiting, but the woman enjoyed a sound sleep, though previously opium was required to produce some slight rest.

In the third case, the drug again caused nausea and vomiting, but was productive of sleep.

Another patient of Dujardin-Beaumetz, being extremely troubled with megrim, took 1 gm. of ethoxycaine in two doses, and soon felt sensations of malaise and nausea; in a little while sleep set in, lasting for two hours. In the afternoon the patient felt so much relieved that he could devote himself to an absorbing work. In the evening the megrim returned, violent but wholly altered in its features.

Chabot made the following observations with the drug on patients: A friend of his affected with violent and frequently returning paroxysms of megrim, received the drug in the dosage and combination referred to above. Vomiting soon set in, but disappeared equally soon. Then the patient felt a sensation of general excitation, an intoxication with some slight vertigo, and an indomitable desire for motion. All these symptoms, however, soon passed off, and the patient felt so greatly relieved that he spent the afternoon visiting the Salon de Peinture. In the evening the headache reappeared.

Our observer also gave ethoxycaine to a young lady of 26 years of age, in whom the paroxysms of megrim returned two or three times a week. The patient could not attend to her duties, vomited often during the paroxysms, and was about to fall into a hopeless condition of anæmia. In spite of several relapses, Chabot succeeded in suppressing these paroxysms by the aid of ethoxycaine. The nausea rapidly disappeared, then the headache itself grew feebler, and at the end of two hours there was nothing left but a dulness in the head. These are the clinical results obtained hitherto with the drug. Any final conclusion

would of course be premature, though it seems as if the drug is destined to be serviceable in certain forms of cephalalgic neuralgia.

#### *GALIUM APARINE.*

Sir William Hooker and Dr. Arnott, in their "Field Book of British Plants," enumerate fourteen families of the genus "galium," of the natural order Rubiaceæ.

The genus takes its name from *γαλα*,—milk which some members of the genus are used to curdle.

They have square stems, leaves in whorls. The predominant colors of the flowers are yellow and white.

The *Galium aparine*, commonly called goose-grass or cleavers, according to DR. GEORGE FOY (*Med. Press*, June 16, 1886), is one of the best known of the genus, and has long been used as a popular remedy for scrofula, cancer, and to stay bleeding. It is mentioned as a remedy for scrofula and hemorrhages by Paulus Ægnetia, and as an aphrodisiac by Dioscorides. Among the Arabian physicians Avicenna, Rhases, and Eben Baither recommended it. Culpepper, Quincy, and Lewis include it in their list of therapeutic agents, and Dr. Robert Hooper (*Dict. Med.*) mentions its use as a remedy for cancer to condemn it. The popular use of *G. verum* as a styptic is mentioned by Gray; but, although he names the *G. aparine*, he does not say if it has any medicinal value.

The plant is very common in English hedges. It flowers in June and July, and has a pretty white flower, and is easily recognized by its globular seed-like bodies with hooked prickles, by which they adhere to the skins of animals, and so become widely dispersed. Its introduction to modern practice is due to Dr. Winn, who, in 1854, read his paper on "Galium Aparine" before the Medical Society of London. His attention was first drawn to the plant by a patient who had long suffered from *lepra vulgaris*, and had taken all the usual remedies in vain. He informed Dr. Winn that he had at last discovered a remedy for this troublesome complaint in a common wild plant of which he did not know the name. Dr. Winn found the plant to be *Galium aparine*, and, on making inquiries, learned that three other persons in that district had been cured by the same remedy. Dr. Winn tried it in nineteen cases of skin-disease,—five were cases of lepra, six of psoriasis, four of eczema, two of lichen, one of inflamed acne, and one of ordinary colored syphilitic eruption. In

nine of these cases the benefit derived from the medicine was very striking. Dr. Bully, of Bucks Hospital, forwarded to Dr. Winn an account of three cases of cancer in which the *G. aparine* appeared to exercise an influence in checking the disease. The preparation used by Dr. Winn was an inspissated juice in *ʒiv*-doses three times a day. A formula for an infusion and ointment is published in Beasley's Pocket Pharmacopœia.

Eight years after Dr. Winn's paper Dr. Ogle recommended the drug as a remedy for epilepsy, and quite recently Surgeon-Major Orwin draws attention to the benefit derived from its use in an obstinate case of psoriasis of the left hand of twelve months' standing, after crysophanic acid, tar ointment, arsenic, etc., had been tried in vain. The rash disappeared by the use of *G. aparine* taken as an infusion and externally applied as a poultice. As there is no difficulty in securing a supply of the fresh plant, and its time of flowering, which will allow of its easy recognition, being near at hand, it would be advisable to submit the plant to a fair trial, and if found worthy of a place in our list of remedies, its inexpensiveness and habitat should not be allowed to militate against its use.

#### *HAMAMELIS VIRGINICA IN HÆMOPTYSIS AND OTHER AFFECTIONS.*

DR. A. BRONDEL writes to the *Bulletin Général de Thérapeutique*, September 15, 1886, as follows:

"Last year I saw Dr. Boucommont arrest before my eyes two hæmoptyses by means of the fluid extract of hamamelis in doses of 40 to 60 drops repeated three times *pro die*.

"I have employed the same extract successfully in pulmonary congestions, which yielded with admirable promptness to the daily ingestion of 3 to 4 teaspoonfuls of the remedy.

"Besides, I have frequently given and taken myself the extract in the beginning of inflammatory conditions of the larynx or trachea. Combining the extract of hamamelis with aconitine, I could in the latter affection produce a rapid cure.

"In the initiatory phases of rheumatism an hour after absorption of the remedy a marked relief and resolution of the inflammation will take place."

#### *PHYSIOLOGICAL ACTION OF VANILLIN.*

According to DR. GASSET, vanillin, which gives the aroma to vanilla, belongs among

the aromatic aldehydes (aldehydes benzoic, cinnamic, etc.). Many cases of poisoning occur among workers in vanilla and persons who have eaten foods containing vanilla. These are due to vanillin. According to experiments made on frogs, vanillin has a convulsive action, exercised principally on the spinal cord; this convulsive action is succeeded by depressive action, exerted equally on the spinal cord and motor nerves; the sensory nerves remain unaffected. Vanillin has a local irritant action. Hypodermically injected into dogs it raises the temperature half a degree. In frogs,  $\frac{1}{4}$  to  $\frac{1}{10}$  of a grain is a poisonous dose; the toxic dose for higher animals has not yet been determined. Vanillin checks putrid fermentation, and in its physiological properties seems to be a diminutive strychnine. Its best physiological antidote or antagonist is chloral hydrate.

It may be used with advantage as a gastric stimulant, especially in atonic and fermentative dyspepsias. In  $\frac{3}{4}$ -grain doses it may be used as a corrigent for remedies badly borne by the stomach. In case its excito-motor properties are desired, it may be administered in a gummy vehicle in 3- to  $3\frac{1}{2}$ -grain doses. — *Western Druggist*, September 4, 1886.

#### THE USE OF COCAINE IN THE HYPODERMIC TREATMENT OF SYPHILIS.

The pain attending the hypodermic treatment of syphilis, no matter whether calomel, corrosive sublimate, the cyanate or formamidate of mercury is used, is a serious drawback to another equally efficient as convenient mode of medication. This objection becomes especially appreciable in cases where the hypodermic method of treatment for various reasons cannot be supplanted by any other, particularly the inunction cure.

MANDELBAUM reports in the *Monatschrift für Praktische Dermatologie*, 1886, No. 6, two such cases, ladies, in whom, for certain reasons, the treatment had to be kept secret. These patients could be best attended to after office-hours at the physician's residence, the cyanate of mercury being injected according to the requisites of the case. Unfortunately, they proved so susceptible to the pain connected with the operation that the injections had to be abandoned. Induced by the publication of Wölfler of the anæstheticizing action of cocaine injections, Mandelbaum tried the following combination with the greatest success:

R Cocain. muriat., 0.05;  
Hydrarg. bicianid., 0.01;  
Aque dest., 1.00. M.

S.—For hypodermic use as one dose.

At first Mandelbaum injected the cocaine solution first, and then, after two or three minutes, the mercury; later he found the simultaneous exhibition of cocaine and mercury to be more convenient and equally effective.

The assistance of these cocaine injections recommends itself also in the use of other hypodermically applied drugs, with the view to eliminate the attending pain.

#### THE INGREDIENTS OF DIGITALIS.

A short time since, in a communication to the Academy of Medicine, M. LAFON called attention to the differences in the characters of the substances supplied by manufacturers under the name "digitalin," and whilst claiming that the articles supplied by French makers correspond to the requirements of the Codex, of being freely soluble in chloroform, only slightly soluble in ether, and giving a green color with hydrochloric acid, and are therefore really digitalin, implied that German makers always send out something else under the name. This charge has induced the firm of E. Merck, of Darmstadt, to issue a reclamation, containing some interesting information which may be worth putting on record. In the first place it is recalled that Schmiedeberg, in his classical research (*Pharm. Journ.*, v. 741), showed digitalis leaves to contain (1) digitonin, a substance resembling saponin in its properties, without the specific digitalis action, and soluble in water; (2) digitalein, an amorphous glucoside soluble in water; (3) digitalin (Schmiedeberg's), a crystallizable glucoside, insoluble in water; (4) digitoxin, insoluble in water, a non-glucoside, but passing under treatment with an acid, without splitting off of glucose, into toxiresin; and (5) digitin, or passive digitalin, an inert crystalline body. These individual substances are said to occur in different proportions in commercial "digitalins," which would therefore vary accordingly in their therapeutic action. The principal commercial preparations are thus described: (1) "Digitalin, pur. pulv.," or "German digitalin," consists principally of digitalein, with some digitonin and digitalin. Digitalein in consequence of its ready solubility in water is not cumulative in its action, and causes no irrita-

tion when subcutaneously injected. Freely soluble in alcohol, and insoluble in ether and in chloroform. (2) "Nativelle's crystallized digitalin." Physiologically extremely active. In fine white needles, bitter in taste, insoluble in water, ether, and benzol, freely soluble in chloroform. Consists almost entirely of digitoxin, and is cumulative in its action. Typical of French digitalin. (3) "Homolle's amorphous digitalin." White or yellowish-white, very bitter powder, slightly soluble in water and in ether, freely soluble in ninety per cent. alcohol and in chloroform. Consists principally of digitalin with some digitoxin. (4) "Digitalin, pur. pulv. (Merck)." Yellowish-white powder, corresponding in its properties with No. 1. Merck also prepares (5) a "crystallized digitalin" identical with digitin, difficultly soluble in water, more readily in alcohol, and insoluble in ether and in chloroform; as well as (6) "digitoxin," the most poisonous of all the digitalis bodies, cumulative in action, crystallizing from alcohol in concentrically grouped needles, freely soluble in chloroform and in alcohol, and sparingly soluble in ether. Further, the amorphous "digitalins" of the Codex and the Belgian Pharmacopœia are said to consist essentially of digitalin, with some digitoxin, and to correspond to Homolle's amorphous preparation. —*Pharm. Journ. and Trans.*, August 28, 1886.

#### THE PHOSPHATES IN THERAPEUTICS.

LOGEAIT writes in the *Archives de Pharmacie*, September 5, 1886, the following concerning the value of phosphates in the treatment of diseases:

The medicinal worth of the phosphates of lime has hitherto been singularly overrated. The triple phosphate of lime, the biphosphate and monophosphate (acid phosphate), as well as the other principal preparations, such as the chlorohydrophosphate, lacto- and citrophosphates, are gradually disappearing from the field of practice, their places being occupied by the phosphates of potassium and sodium. Very recent observations have yielded the fact that the action of the phosphates of lime is exceedingly uncertain and doubtful, as they cannot be absorbed in the economy. No doubt, says Logeait, the soluble phosphates of lime remain dissolved as long as they are in the stomach, and the insoluble preparations become dissolved by the action of the gastric juice; but as soon as they have passed into the duodenum, the alkaline bile precipitates them at once, and renders them insoluble

again. Hence through the greater part of the entire intestinal tract they act as totally inert matters, and are finally rejected with the rectal discharges.

It is different, however, with the phosphates of potassium and sodium, which are equally soluble in acid, alkaline, and neutral menstrua; they remain dissolved during their entire passage through the digestive channels, and are consequently resorbable.

The absorption of phosphates of lime is by no means indispensable to the explanation of the formation of osseous tissue. We can logically presume that the soluble salts of lime alone are absorbed, which precipitate neither in an acid nor an alkaline medium.

These salts meet, in the deeper channels of the economy, the phosphates of sodium and potassium, arriving with the same conditions of solubility, and form thereby double decomposition phosphate of lime.

#### URINARY INCONTINENCE OF CHILDREN TREATED BY ANODYNES PER RECTUM.

It is safe to say that the modes of treatment usually recommended for this distressing infirmity are frequently ineffective and disappointing. In the *Boston Medical and Surgical Journal*, September 16, 1886, DR. EDWARD T. WILLIAMS states that for the last year or two he has been employing, with complete success thus far, the use of anodynes by the rectum in the form of injections, suppositories of morphine, belladonna, and atropine, and he states further that he has not only cured six cases by these means, but temporarily relieved many more who have passed out of sight during treatment. He finds that morphine alone relieves for the time being, but does not cure. Belladonna and atropine are curative when taken long enough, although he finds them to be better borne in combination with a little morphine, which counteracts some of their bad effects and enables them to be given more continuously. Furthermore, the requisite dose of belladonna is smaller when combined with morphine. When these medicines produce headache or undue nervous excitability, he uses the bromides as a corrective or suspends their administration for a time. He has found no case where they could not be borne when properly given.

As to the mode of administration, a fifteen-grain suppository of cocoa-butter is most easily handled. They should contain a proper amount of extract of belladonna and morphine. For a child 5 years old, say, one-

eighth of a grain of belladonna extract, and one-sixteenth grain of morphine; but the doses must be carefully adapted to the particular case in hand, beginning with a small dose, with a smaller relative proportion of belladonna, and increasing the latter and diminishing the morphine as toleration becomes established.

If an enema or clyster be preferred, it should consist of about a drachm of lukewarm water, with a few drops of atropine and morphine solution added, and administered with the small hard-rubber syringe (No. 2), especially designed for the purpose. The old-fashioned clyster of starch-water and laudanum is absurdly out of date. Dr. Williams has used nothing for years but morphine and warm water, mixed as for a subcutaneous injection, only that the water should be tepid and not exceeding a drachm in amount. Dr. Williams uses two solutions. The first consists of one-sixth grain of morphine and twenty minims of water. The dose by drops therefrom is the same as that of laudanum, which makes it especially convenient for the nurses. The other is one-sixtieth grain of atropine to twenty minims of water. Reckoning one-sixtieth of a grain as an average commencing dose for an adult, the dose for a child may be graduated by drops precisely as with laudanum. For a child 5 years old, then, as an enema, one might give for a commencing dose from 3 to 5 drops of each solution, mixed with a teaspoonful of warm water. These doses may be differently combined or altered in any way to suit a particular case.

#### PIPER BETEL LEAVES.

According to MESSRS. JEHE & CO. (*Handelsberichte*), a supply of the leaves of the *Piper betel* L., which are used in India for chewing with areca-nut, has recently been imported into Germany. An essential oil obtained from the leaves by distillation at Samarang by Schmitz, has been credited by him with having given good results in the treatment of catarrhal disorders and as an antiseptic. This claim has been substantially confirmed by Dr. Kleinstück, of Jena. The oil, which seems to be of an aldehyde nature, is said to oxidize with extreme rapidity, losing at the same time its characteristic ethereal odor and therapeutic properties. Great care will, therefore, be required in the transit of the leaves if the oil is to be distilled in Europe.

#### THE DIRECT ACTION OF CALCIUM, SODIUM, POTASSIUM, AND AMMONIUM SALTS ON THE BLOOD-VESSELS.

DR. H. G. BEYER has been investigating the action of the above salts on the blood-vessels, and publishes his experiments in the *Medical News*, September 4, 1886. He formulates his conclusions as follows:

1. Calcium salts cause the vessels to contract by virtue of their stimulating influence on the vaso-motor ganglia.
2. Sodium and ammonium salts excite, first, the ganglia of the vaso-dilators, next those of the vaso-motors; hence producing at first dilatation and afterwards contraction of the vessels.
3. Potassium salts stimulate the ganglia of the vaso-dilators only, and consequently produce dilatation. If, however, as was shown in two observations, the dilatation which they produce is followed by contraction, this contraction is so extremely slight that it may practically be neglected. Therefore any stimulating influence on the vaso-motor ganglia which they might possess is insignificant when compared with that which they exert over the vaso-dilators.

#### CLINICAL EXPERIENCE IN TYPHOID FEVER.

DR. AUFRECHT, chief of the City Hospital of Magdeburg, favorably known to the profession both as clinician and as author, publishes from time to time, under the title of "Pathological Communications," a little pamphlet, intended to represent the clinical experience gathered at that institution. The third number issued this year, treating of typhoid fever and its therapeutics, deserves to be carefully examined.

The clinical material embraces five hundred and fifty-one cases of typhoid fever that during the last six years came under Aufrecht's observation. Of these fifty-eight (*i.e.*, 10.5 per cent.) died, four even within twenty-four hours after admission to the hospital.

Aufrecht declines to regard the elevation of temperature alone as an indication for the bath, and employs the latter only in patients who, together with a temperature of 40° C., present a small but frequent pulse, and either nervous ataxia or delirium. Cases marked by a good, firm pulse, and freedom from nervous symptoms, were invariably found to take a favorable course without baths, in spite of the height of the temperature, while, on the other hand, the bath employed in accordance with

the above indications proved also a constant success. Frequently a single bath sufficed to reduce the temperature  $2^{\circ}$  to  $2\frac{1}{2}^{\circ}$  C., to raise the working energy of the heart, and to eliminate threatening nervous symptoms. The number of baths usually required never exceeded five or six, given on three consecutive days. The author emphasized the maxim that in typhoid fever the mere elevation of temperature does not justify the employment of baths.

The routine practice in the Magdeburg Hospital is to give the typhoid fever patients a weak solution of muriatic acid (15 drops; 6 oz. water with 1 oz. syr. simpl.), an ice-bag placed upon the epigastric region, and another one on the head in case of cephalalgia. Most patients received also a tablespoonful of Hungarian wine every two hours, a practice which Aufrecht, however, does not approve of in private patients, these having generally a greater amount of albumen in store than hospital patients.

If the evening temperature is beyond  $39.5^{\circ}$  C., and the above indications for the use of the bath are absent, the patient receives, beginning with the next morning, daily,  $7\frac{1}{4}$  grains of hydrochlorate of quinine. Except these small doses of quinine, which only exceptionally in rare cases were doubled, Aufrecht used no other antipyretic. To prevent decubitus every patient is at the very beginning of the treatment placed upon a water-bed. In this manner Aufrecht has avoided all cases of decubitus for the last two years.

The febrile dryness of the tongue may, our author believes, lead to grave consequences. The mucous membrane is gradually being broken, swallowing is rendered painful, and the patient refuses or is unable to take food. Speaking is likewise rendered difficult if not impossible for the same reason. Nor is it unlikely that through the broken mucous membrane of the larynx and pharynx bacteria penetrate the submucous tissues, and give rise to various grave local and even constitutional disturbances. This difficulty cannot, as might be presumed, be obviated thoroughly even by constantly-repeated draughts of water. Aufrecht applies, as soon as the tongue begins to dry up, glycerin, every two hours or more often, to it in so thick a coat that a part of the drug, through the induced motions of swallowing, reaches the hindmost portions of the pharynx and larynx. This procedure protects the parts from tears and crust formations.

Diarrhoea was combated by opium if the

stools exceeded the number of four in twenty-four hours. The drug is given in powder form, in  $\frac{1}{2}$ -grain doses, two to four times daily.

In intestinal bleeding the liquor ferri was found to be wholly useless and, besides, irritating to the digestive functions. To decrease the peristaltic movement the patient received  $\frac{1}{4}$  of a grain of morphine and two Pravaz syringes of a watery solution of ergotine (1 to 10). The latter solution is to be absolutely fresh, as in older ones germ-formation readily takes place. Friedländer's sterilized hypodermic solution will, of course, henceforth be exclusively used.

The vomiting often observed in typhoid fever patients in connection with peritonitic symptoms is by Aufrecht referred to intestinal ulcerations encroaching upon the peritoneum, and is treated by morphine given per os, or in obstinate cases hypodermically. This medication exhibited at the very beginning of the vomiting may possibly, in many cases, prevent a peritonitis, of which the vomiting is simply a premonitory symptom.

An especial value is placed on morphine in the cases marked by intense delirium.

Meteorism is best treated with ice applied to the epigastric region, and with small doses of morphine.

In conditions of collapse the hypodermic injection of camphor is unquestionably the most efficient remedy. The oil of camphor (6 camphor—24 oil of sweet almonds) is a very eligible preparation for this purpose. Aufrecht uses as much as 30 grains of camphor—*i.e.*, ten Pravaz syringes daily—even for several successive days. Abscesses have never been observed after these injections of oil of camphor.

Dr. Friedländer, of Berlin, the discoverer of the sterilized hypodermic solutions (*vide* leading article of August issue of the THERAPEUTIC GAZETTE), exhibited his preparations at the exhibition of German physicians and naturalists meeting in Berlin on September 18, and, as was to be anticipated, was the recipient of unqualified praise and commendation from all quarters. These sterilized solutions will be certain to meet with a warm reception also in this country.

In this connection we beg to state that Dr. Friedländer, who is a chemist of high standing in the German metropolis, is the proprietor of Simon's Apotheke, and has, as we understand, good reasons not to be mistaken for another gentleman having the same name who also owns an apothecary's shop in Berlin.

### THE INFLUENCE OF ALCOHOL ON THE FUNCTIONS OF THE STOMACH.

DR. GLUZINSKI has just published in the *Deutsches Archiv für Klinische Medizin*, 1886, vol. xxxix, B. No. 9, the results obtained by his experiments instituted to ascertain the influence of alcohol upon the gastric functions. We epitomize his main conclusions by the following theses:

1. Alcohol disappears quickly from the stomach.

2. Aldehyde cannot be recovered, and alcohol very probably enters, as such, the circulation.

3. The digestion influenced by alcohol can be divided in two distinct periods,—viz., one, during which alcohol is still present in the stomach, and another after its disappearance.

4. The first period is characterized by an impeded or rather slowed state of digestion of albuminates, the second by the secretion of an energetic and concentrated gastric juice.

5. The mechanical working power of the stomach is moderately diminished.

6. The secretion of gastric juice after completed digestion lasts considerably longer than without the presence of alcohol.

7. Under the influence of alcohol larger quantities of fluid collect in the stomach, and assume through the action of the bile a yellowish coloration.

Comparing these results with daily experience, according to which alcohol is known to facilitate digestion, especially after a copious ingestion of food, it must be conceded that alcohol in small doses actually exerts a favorable influence upon the functions of the stomach. Especially to be noticed is the increased quantity of free muriatic acid which, at the time when the alcohol itself has long left the stomach, effects the digestion of large quantities of albumen. The momentary slowing of digestion during the first period after the ingestion of a small quantity of alcohol, such as a glass of cognac, is of too short a duration to be at all considered. The experimenter even saw that 100 c.c. of twenty-five per cent. alcohol left the stomach in fifteen minutes, and that instead of a slowing of digestion the secretion of an active gastric juice took place. The impediment to the mechanical functions of the stomach is, after small quantities of alcohol, likewise too trivial to require any consideration.

Different, however, are the results obtained after the use of larger quantities of alcohol. The slowing of digestion is now considerable; the mechanical functions are distinctly im-

peded, necessitating a longer stay of the food in the stomach. Hence it is clear that alcohol in large doses decreases the quickness of digestion.

To obtain the salutary effects of small doses of alcohol it is necessary to administer them some time before the meal, so as to bring the food at once into the second period which, as stated above, is favorable to digestion.

Another series of experiments made to ascertain the influence of alcohol upon digestion in a pathologically altered stomach claims likewise our attention, and can be thus resumed:

The use of stronger alcoholic drinks is inadvisable in conditions of an abnormally increased or decreased acidity of the gastric juice. In cases calling for excitantia, alcohol is nevertheless to be given, though best some time before the meal for reasons intimated above.

These results throw no favorable light upon the conducive virtues of the numerous pepsin-containing alcoholic preparations, the use of which is recommended in all cases of an impeded digestion without regard to the cause. Besides, it is rather likely that alcohol precipitates pepsins, and ought for this reason not to be associated with the latter.

### CONTRIBUTION TO THE ACTION OF URETHAN EMPLOYED SUBCUTANEOUSLY.

It seems as though urethan is but slowly making its way into the practice of neurologists, though the favorable reports concerning its sedative and hypnotic effects, formerly sparse and possibly unreliable, begin now to be announced somewhat more frequently and from more authoritative sources.

Not long ago, Dr. Rottenbiller, who had given urethan a very fair trial, spoke in very favorable terms of the drug, especially of its hypodermic application, in the *Centralblatt für Nervenheilkunde*, 1886, No. 10. Induced by Rottenbiller's eulogization of the remedy, DR. WILHELM KÖNIG, of Dalldorf, instituted a series of clinical experiments with urethan, and communicated the results obtained to the *Centralblatt für Nervenheilkunde*, June 15, 1886.

Urethan was exclusively tried on patients with a high nervous excitation; as for lighter cases, remedies of a prompter and safer nature are more suitable, and hypodermic medication besides is a relatively inconvenient measure.

Ten paralytic patients were, for the sake of

an easier superintendence, placed together in one room, and received for seven continuous days, at 8 o'clock P.M., one to three Pravaz syringefuls of a fifty per cent. solution of urethan, each syringe containing about seven grains of urethan.

The effects of this medication were still less satisfactory than those obtained by König from the internal administration of the drug. Besides, some patients soon refused to allow any more injections, partly because they were in no way benefited by them, and partly because they were annoying and painful.

König found that the patients came but very slowly and late under the influence of the hypnotic, hours usually passing before sleep set in. In one instance only the patient fell asleep at 8.45 P.M. The following table represents the percentages of obtained successes :

Dose.	Successes.
1 syringe (7 grains of urethan).....	47 per cent.
1½ syringes (10 grains of urethan).....	25 per cent.
2 syringes (14 grains of urethan).....	33 per cent.
3 syringes (21 grains of urethan).....	0 per cent.

König abandoned the experiments on the seventh day, feeling convinced that in conditions of high-graded excitation the action of the drug, in doses safe and convenient to administer, was not sufficiently energetic to warrant its employment.

König also mentions that in nearly all patients who received the drug the appetite was found to be decreased on the third day. Other secondary effects, though, were not observed.

These rather negative results obtained with urethan recall the equally unsatisfactory experiments made with the same drug by Dr. Bock, of Pankow, as reported by the observer himself in the February issue of the *GAZETTE*, and differ strangely from the alleged successes of Von Jaksch, Rottenbillier, and others. As long as this state of uncertainty regarding the actual therapeutic worth of urethan lasts, the practitioner ought not to feel called upon to relinquish the old and tested stand-bys for a new and unreliable agent.

#### ON PELLETERINE IN CHILDREN.

It is known that pelletterine sometimes produces in adults symptoms of intoxication, and the question how does the drug act on infants is therefore a practically interesting one. MÉPLAIN writes to the *Bulletin de Thérapeutique*, July 15, 1886, that having been in charge of a child 2½ years old affected with tænia, in

which all other anthelmintics proved useless, he prescribed 1 grain of pelletterine to his little patient, and was gratified to find the drug doing its work. The worm passed, and no untoward symptom was observed in the child. Méplain says that a small dose of pelletterine suffices to expel the tænia in a child, and children seem comparatively less susceptible to the toxic action of the drug than adults.

The drug, however, concludes the writer, ought to be of an irreproachable activity.

#### THE INTRA-UTERINE STEM IN THE TREATMENT OF FLEXIONS.

At a meeting of the Chicago Medical Society, held June 7, 1886, PROFESSOR A. REEVES JACKSON read a paper entitled "The Intra-uterine Stem in the Treatment of Flexions," exhibiting the stems used (*Chicago Medical Journal and Examiner*, August, 1886). The essayist began treating uterine flexions with the stem pessary in 1870. Prior to that time the only methods he had employed were gradual dilatation and incisions. The results were so unsatisfactory that he sought for a safer and more successful method. Having received the impression that the use of the stem pessary was more hazardous than either the dilating or cutting plans, he commenced its employment with misgiving, and did not rely wholly upon it, but preceded it with either gradual stretching or slight incisions. In two cases this mixed method was followed by pelvic abscess, a sequence which he had never observed when the stem alone had been used. All cases of uterine flexion are not accompanied by dysmenorrhœa or sterility, yet when there exists a relationship between these symptoms and an existing flexion, the latter must be looked upon as a mischievous factor, and one that should be removed. He had never treated any case of flexion in which dysmenorrhœa was not present, although co-existent barrenness has been frequently an additional incentive to the patient to undergo efforts at cure.

He preferred Chambers's bifurcated vulcanite instrument, although the divergence of the branches *below* the internal os uteri was a radical defect in the instrument as ordinarily used. Frequently the branches should be closed so that the stem might be practically single in that portion which traverses the cervix. His method is as follows : A flexion and its direction being diagnosticated, a flexible bougie is passed through the bent portion of

the canal and quite to the fundus. The depth of the canal being carefully noted, a pliable stem, consisting of the distal portion of the same, or a similar bougie, one-third of an inch shorter than the ascertained depth of the canal, is selected for introduction. A flange or bulb is formed upon the outer end of the stem by rolling upon it a section of rubber tubing. The woman being placed on the back, in Simon's position, and the os uteri exposed with a speculum, the stem, either grasped with a dressing forceps or mounted upon the end of a piece of pointed wire, is passed entirely into the uterus. A large tampon of cotton, moistened with slightly aluminized glycerin, is pressed against the bulb of the stem, and allowed to remain one or two days. The tampon is removed and replaced at suitable intervals, until the tendency of the stem to leave its position disappears. After this yielding stem has remained from one to three weeks, according to the degree of tolerance manifested by the uterus, it is removed, and a thicker one put in its place. This likewise is permitted to remain a week or two, and is then replaced by a Chambers stem. While not very much, or, indeed, any change of shape is to be expected in consequence of the use of the flexible stem, yet, in several instances, a very considerable alteration took place within a few weeks, or even a few days, and in a few cases it was found unnecessary to resort to a rigid instrument at all. Usually, however, it had been necessary to use an inflexible instrument for from three months to a year, not continuously, but for periods of three or four months, with an interval of a week or two, during which the stem was removed in order to test the degree and permanence of the improvement. The feature of this treatment, which is essential to its safety and success, is its slow and gradual conduct, and the non-observance of this necessity has been the cause of dangerous results and failures to cure.

The drawbacks attending this method of treatment were: 1. Difficulty in retaining the instrument in position; 2. Pain; 3. Hemorrhage; 4. Pelvic inflammation; all except the first being common to all other methods of treatment. A table comprising the details of 64 cases treated by the intra-uterine stem alone was given, showing the ages and social conditions of the patients, the direction of the flexion, and the result of the treatment. Of the entire number, 42 occurred in married and 22 in single women. Of the former, 8 had borne children; the other 34 were sterile. Of

the latter, 8 subsequently bore children. A cure of the flexion followed in 40; of the remaining 24, 4 were improved and relieved of dysmenorrhœa. In 20 the result was unknown. The ages of the patients ranged from 19 to 39 years. The uterus was ante-flexed in 50 and retroflexed in 14.

In conclusion, the author said, "I believe the principle of the intra-uterine stem in the treatment of flexions to be correct; and it need not be dangerous, at least, no more dangerous than any other effective method. I further believe that by its use more cases of uterine flexion can be cured than by any other means at present in vogue. The conditions of both safety and success are watchfulness, patience, and slow progress."

#### NOVEL TREATMENT OF DIPHTHERIA BY DIGITALIN AND SULPHIDE OF CALCIUM.

We condense the following important therapeutical considerations from the *Archives de Pharmacie*, September 5, 1886:

DR. GALICIER some time ago eulogized a novel form of treating diphtheria, which, it seemed, had given excellent results. A paper appearing in the *Moniteur Thérapeutique* of August, 1885, by Dr. Cug, of Pau, in which this physician claims to have saved two cases of diphtheria,—two boys, aged  $4\frac{1}{2}$  years and 5 months respectively,—calls our attention anew to the plan proposed by Dr. Galicier. This physician orders the following pills:

R Sulphide of calcium, 0.05;  
Digitalin, 0.001;  
Arsenate of quinine, 0.001. M.  
Fiant pil.

S.—Take one every hour, day and night.

Both Cug and Galicier claim that no intoxication was ever produced by this remedy.\* The great general intoxication probably prevents any further intoxication from the part of digitalin.

The pills are usually continued for a couple of days.

#### LOCAL ANÆSTHESIA FOR ELECTROLYSIS.

DR. FRANKLIN H. MARTIN, Professor of Gynæcology in the Chicago Polyclinic, writes

\* To give 2 cg. of digitalin in twenty-four hours from the beginning to a child seems in our judgment a rather hazardous treatment, provided the drug is not inert, as many specimens in the market actually are.

to the *Medical Record*, October 9, 1886, as follows: "Where it is necessary to use a very strong current of electricity for purposes of electrolysis, or any other purpose, and a reliable means of measuring the current, other than by the sensations of the patient, is at hand, it is very desirable oftentimes to have some means of producing anæsthesia. Especially is this the case with women who have been brought to an anæmic and nervous condition from menorrhagia coincident with a fibroid growth of the uterus. In these cases, where electro-puncture is used as a means of removing the growth, or even where the somewhat milder electrolytic current is employed for the purpose of causing absorption of inflammatory exudates, there is a very disagreeable burning sensation experienced at the positive sponge electrode. By utilizing the properties of the galvanic current, discovered by Haertner, viz., the direct transference by the galvanic current of particles in solution through permeable bodies in a direction from the positive to the negative pole of the battery (the *cataphoric* action of Du-Bois Raymond), a very satisfactory condition of local anæsthesia can be accomplished. The method adopted is as follows: Before applying the positive sponge electrode to the surface, moisten the sponge with a one-fourth of one per cent. solution of muriate of cocaine. As the current is turned on, it will be found that the absorption of sufficient amount of the cocaine is immediately promoted to produce a complete state of anæsthesia of the surface beneath the electrode. This, of course, does not affect the point of application of the negative pole,—the point of introduction of the needle. Cocaine can still further be utilized here by injecting hypodermically a small quantity of the aqueous solution at the point of introduction of the needle through the skin, or by applying a solution of the oleate upon the mucous membrane of the vagina or uterus, if the needle is introduced in this location. By bearing these simple facts in mind, electrolysis for fibroid tumor can be made familiar without the necessity of administering a general anæsthetic."

#### ON SALICYLATE OF BISMUTH.

DR. SOLGER publishes in the *Deutsche Medicinal Zeitung*, No. 22, 1886, some interesting therapeutic facts concerning the salicylate of bismuth, a drug which appears worthy of our attention.

Solger first exhibited the remedy to a Ger-

man physician, who for ten years had suffered from frequently returning pains in the region of the sigmoid flexure. Laxatives, medicinal waters, diet, electricity, nervines, in brief, everything that therapeutists could suggest, were either useless or even deteriorated the condition of the patient. Using for fourteen days salicylate of bismuth, in doses of 12 grains three times daily, the patient got rid of his pains and recuperated fully his broken-down health. A return of the pains some time after yielded also to a fourteen days' medication with salicylate of bismuth.

Later, Solger has given the drug to numerous patients, both in private and in hospital practice, and has obtained surprising results with it. He has, however, reduced the average dose from 12 grains to 8 to 10 grains, without obtaining any less satisfactory results. The following formula represents, according to Solger, the most effective and convenient mode of employing the drug:

R Bismuth. salicyl.,  
Sacchari lactis, aa ʒvi. M.  
F.—P., divide in p. æq. No. 40.  
S.—One powder every eight hours.

The drug occasions no inconvenience, either when taken on an empty stomach at six o'clock in the morning, or after dinner at two o'clock, provided the dry powder is washed down with a little water. Given in wafers, the drug is apt to produce some gastric irritation.

Solger gave the drug principally in chronic diarrhoea and intestinal catarrh, especially after other remedies had failed. An aged lady, who, suffering from a chronic intestinal catarrh and involuntary discharges from the bowels, had been reduced to a stage of profound emaciation, and had for years been confined to the bed, regained in three months her health by the use of salicylate of bismuth. In another case, a demented woman, troubled with chronic diarrhoea and incontinence of urine, took the drug for several months, and recovered not only from her grave physical ailments but also gained a certain low degree of intelligence. In phthisical subjects the drug proved likewise very valuable in arresting the exhausting diarrhoeas and inducing a state of comparative well-being.

Noxious effects can only appear in cases of intestinal obstruction combined with a low nutrition. Among the symptoms of an incipient intoxication Solger mentions nausea, a furred tongue, and pressure in stomach and bowels. The tongue gives an especial warning by pre-

senting a gray appearance, with a black streak in its longitudinal axis. The trouble is, however, easily relieved by a good dose of castor oil, or any other laxative, and is no indication for the suspension of the drug.

In the ectatic conditions of the stomach, and especially in stenosis of the pylorus, the drug is contraindicated. Investigating these beneficent effects of salicylate of bismuth in the mentioned gastro-intestinal affections, we cannot attribute them to the (moderately) astringent properties of bismuth, but are justified in viewing the disinfectant influence of the drug upon the intestinal contents as its principal therapeutic factor. In this respect the drug can be placed on a line with naphthalin, only that the latter drug is not nearly so well borne by the stomach as salicylate of bismuth. Both drugs check the profuse propagation of bacteria and micrococci in the intestines, and thus produce curative effects in the affections mentioned.

#### *BALSAM OF COPAIBA IN GONORRHOEAL OPHTHALMIA.*

DR. S. HAYNES, of Saranac, N. Y., writes to the *New York Medical Record* (October 9, 1886) that he was called to see an infant, four days old, who was suffering from conjunctivitis, contracted from the mother, who had gonorrhoea at the time. The inflammation had existed two days, and the cornea was found covered with thick pus, and the eyelids were so swollen that they could be separated with difficulty even when the child was under the influence of chloroform. For several days the remedies used seemed only to hold the disease in check, and the infant meanwhile was rapidly losing flesh. Severe stomatitis was also developed. Applications were now made of balsam of copaiba to the temples, the external surface of the lids, and above the eyebrows three times a day, a little being occasionally inserted between the lids. The pus was carefully removed every hour by pledgets of cotton, wet with solutions of alum or sulphate of zinc, and fresh butter was applied to the edges of the lids every night. From the commencement of the use of the balsam a marked improvement was noticed, and in three or four weeks the cornea was perfectly clear and free from disease, and the child had gained in flesh. The case had everything against it, as the parents lived six miles away and could be visited only occasionally, the mother was confined to bed for a great part of the time, and the family were ignorant and

suffered from the want of many of the necessities of life. Dr. Haynes states that the use of the balsam of copaiba was suggested by an article which he read some time ago, but he has forgotten both the name of the writer and the medical journal in which the article appeared.

#### *OXYMEL SCILLÆ IN WHOOPING-COUGH.*

DR. NETTER has recently read a paper before the Congress de l'Association française pour l'Avancement des Sciences (*vide Archives de Pharmacie*, September 5, 1886), which, like all other therapeutic suggestions pertaining to pertussis, recommends itself to the notice of the practitioner.

Netter advocates the use of the oxymel scillæ, prepared strictly according to the prescription of the Pharmacopœia, as an efficient remedy in whooping-cough. He gives the preparation pure without any excipient, and orders it in the following doses :

For suckling infants, 20, 40, to 60 drops in twenty-four hours, in the intervals of nursing.

For children of about 2 years of age, 4 to 5 teaspoonfuls, taken afternoon and evening, in intervals of six minutes.

For children 3 years of age or older, 6 to 7 teaspoonfuls, taken similarly as above.

For adults, 8 to 9 teaspoonfuls, taken in the same manner.

His observations at the Hospital of Nancy went to show that the remedy administered under these conditions proved very efficacious. It is indispensable that the stomach be empty when the drug is taken, and the latter may be continued until the disappearance of the paroxysms.

Dr. Rémy confirmed Netter's observations, and stated that under this medication whooping-cough could be cured in about a week's time, and sometimes even sooner than that.

#### *FAILURE OF LARGE DOSES OF ANTI-PYRIN IN A CASE OF SUNSTROKE.*

DR. M. SINGER, house surgeon of St. Mary's Infirmary, Galveston, Texas, reports the following case in the *Medical Record*, September 25, 1886 : "A man, name unknown, aged about 40, was brought to St. Mary's Infirmary on August 5, 1886, at 6 P.M. At about three o'clock in the afternoon he had been found lying unconscious in the street by a police officer, who, supposing him to be drunk, took him to jail. Two hours later the jailer, noticing the deep coma and intense bodily heat, had him

conveyed to the hospital. Upon admission the pulse was 120, full and strong; respiration 40, stertorous, with short intermissions about every five minutes; temperature 108.4°. Skin hot, dry and parched; coma complete; pupils slightly contracted. I gave 50 grains of antipyrin under the skin, applied sinapisms to extremities, and ice on the head. At 7 P.M. the patient's condition was unchanged, every symptom as before. Gave 10 grains of antipyrin under the skin.

"At 8 P.M. the patient's general condition remained the same, except that he had passed his water in bed. Pulse 122; temperature 108.8°. Gave hypodermic 20 grains of antipyrin. At 9.30 P.M. symptoms unchanged, except for the temperature, which now was 109.8°. The excessive heat of skin could well be felt through the patient's shirt and the bed-sheet. Gave hypodermic 20 grains of antipyrin.

"At 11 P.M. pulse 140, weak; temperature 109.8°; respiration 18, stertorous, puffy, sometimes catching and irregular.

"Patient died at 11.30 P.M. Temperature at time of death 110°; post-mortem temperature, taken three-quarters of an hour after death, 108.5°; pupils slightly dilated. The temperature in this case was taken in the axilla. No other antipyretic measures were employed but those mentioned above. I have used the same preparation of antipyrin in many febrile conditions, and in doses of from 20 to 30 grains, without failing at any time to reduce the fever heat. In this case, however, 100 grains of the drug, given under the skin, within a period of three and a half hours, proved to be utterly worthless. No diaphoresis was produced at any time after the administration of the remedy."

#### ON INSPIRATIONS OF COLD AIR IN FEVER.

DR. IWAN WOITKEWITSCH communicates to the *St. Petersburg Med. Wochenschrift*, No. 24, 1886, his views on the value of cold air inspirations in febrile affections. His observations were made in seventy-one instances, and comprise cases of typhoid fever, pleurisy, and pneumonia. The air was cooled by means of an apparatus constructed for the purpose by Woitkewitsch, and applied to the patient for fifteen to forty-seven minutes. The observer draws the following conclusions:

1. The febrile temperature was lowered by the cold air only immaterially and for a short time.

2. Pulse and respiration, however, were considerably slowed.

3. The general subjective state of health and sleep improved likewise, though for a short time only.

4. The phenomena of the bronchial catarrh decreased to an eminent degree under the influence of cold-air inspirations.

5. The inspirations exerted a favorable influence upon the general course of the disease, and in no instance proved to be injurious.

#### THE PROPER USE OF ERGOT IN OBSTETRICAL PRACTICE.

From an elaborate paper with the above title, read by DR. FRANK HAMILTON POTTER before the Buffalo Obstetrical Society, the author draws the following conclusions (*Buffalo Med. and Surg. Journ.*, September, 1886):

1. Ergot is a drug which in any of its preparations tends to deteriorate rapidly, and should never be used excepting when prepared from a pure and fresh specimen.

2. It is a stimulant to the tubular and non-striated muscular structures of the body, causing them to contract.

3. It acts especially upon the muscular structure of the uterus, throwing it into a state of tonic spasm.

4. Its action on the uterus is, however, uncertain; sometimes it contracts the entire organ, at others only a small part of it.

5. If the entire organ is contracted, labor may be delayed through the rigidity of the os, and the child destroyed by the interference of the placental circulation.

6. Or the contractions may be so powerful as to force the child at once into the world, causing any or all of the lacerations of the soft parts of the mother.

7. The life of the child may be endangered, also, through absorption of the essential oil of ergot.

8. If given after the birth of the child, and before the expulsion of the placenta and membranes, it may prevent the removal of the latter, and thus be indirectly a cause of puerperal septicæmia.

9. It may act in a similar manner in cases of abortion, actual or threatened, and cause a similar result.

10. The proper use of ergot in obstetrical practice is limited to those cases in which, after the expulsion of the placenta, the uterus refuses to contract, or, having once contracted, shows a tendency to secondary relaxation. Even in these cases, however, reliance should

not be placed upon it alone, but its action should be supplemented by the other means used to provoke uterine contraction.

#### THE ANTIRHEUMATIC VIRTUES OF ANTIPYRIN.

We abstract from the inaugural essay of Dr. EICH (Basel, 1886) on the antirheumatic virtues of antipyrin some points of general interest.

Of thirty-six cases treated by Dr. Eich (acute and chronic articular rheumatism, acute muscular rheumatism, rheumatismus vagus) all patients but two could be discharged as cured. In one of the two cases the failure was predicted on account of the great anatomical alterations produced by the chronic process in the joints, and in the other salicylic acid given alternately with antipyrin proved likewise useless. Eich concludes from the results obtained that antipyrin owns an exceedingly prompt and reliable antirheumatic power, and is in this respect in no way inferior to the preparations of salicylic acid. Still, Eich continued, the curative action of antipyrin is as little infallible as that of salicylic acid, and appears to possess no greater power to prevent cardiac complications than the latter remedy. In the treatment of affections of the endocardium and the serous membranes Eich saw likewise good effects from the drug. The absence of all secondary effects, however, renders antipyrin more eligible than the preparations of salicylic acid; at least the two remedies can conveniently supplement each other in case one should fail.

As to the dose, Eich gives at the beginning from 60 to 90 grains, and later only 30 grains *pro die*.

#### ELECTROLYSIS IN GYNÆCOLOGICAL SURGERY.

At the meeting of the American Gynæcological Society, held in Baltimore last September, Dr. BAKER read a paper on the uses of electrolysis in gynæcology (*N. Y. Med. Journ.*, October 16, 1886). The speaker referred more particularly to the use of electrolysis in cases of fibroid tumor, and laid down the following rules for the performance of the operation: It should not be employed within a week before or after menstruation. An anæsthetic should be administered. It was better to use electrolytic needles for both the positive and negative poles; the operator should be absolutely sure of the cleanliness of the needles;

the needle should be deeply buried in the tumor, in order that the current might be insulated from the parts outside of the growth; the insertion of the needle should be made at the most prominent part of the growth, whether that was in the vagina or in the abdominal wall; the needles should not be too nearly approximated; if both needles were properly placed, the position of the two poles made no difference; the circuit being completed, the number of cells should be gradually increased from four to twenty or thirty (a more exact means of determining the strength of the current would be the galvanometer, but this had not given him accurate results); the length of time during which the application was continued should be from ten to twenty minutes, and should be determined by the character of the pulse. When the pulse became slower and weaker than normal, the number of cells should be diminished or the current discontinued. The current should be diminished gradually, and the wires should be disconnected at the battery before the needles were removed. The applications should not be made at the surgeon's office. After the application, the patient was to be put to bed, where she was to remain for one week. With such precautions, the speaker had never seen shock after the operation. A single treatment was often all that was necessary. He had never found it necessary to make more than three applications, and the latter number in only one case. There should be an interval of at least from one to three months between the applications. The use of electrolysis was also of service in the treatment of inflammatory effusions. Before resorting to electrolytic puncture, the application of the galvanic current should be tried, as it did not require an anæsthetic, and avoided the slight risk which accompanied even small wounds.

The following conclusions were presented:

1. Electrolysis was a useful agent in the treatment of certain cases of fibroid tumors of the uterine walls and of chronic circumscribed perimetrial effusion.
2. When applied to fibroid tumors of the uterus, electro-puncture was a most reasonable and efficient method.
3. In the treatment of fibroid tumors by this agent, it was unnecessary to apply it often.
4. Cases of perimetrial effusion to be treated by this method should be selected with care in reference to the absence of all acute symptoms.

In the discussion which followed, Dr. CHADWICK stated that he had tried electrolysis ten

years ago in one case of fibroid tumor, introducing the needle through the abdominal wall. This had caused a smart attack of peritonitis. During the following year there was no decrease in the size of the tumor. He had also seen abscess follow its use.

DR. ENGELMANN said that the dangers mentioned by Dr. Chadwick were those which were liable to follow puncture through the abdominal wall. By puncturing through the vagina, and, if possible, through the tissue of the uterus, the dangers of inflammation which accompany abdominal puncture were avoided.

DR. JAMES B. HUNTER, of New York, could not say that he had seen one case of fibroid tumor permanently relieved by electrolysis. In one case, in which it was freely used by Dr. Freeman and himself, he had subsequently removed the tumor by hysterectomy, the patient making a good recovery. He could find no evidence of the effect of the current on the tissue of the fibroid.

DR. MANN had employed this agent in one case, plunging one needle into the tumor from behind through Douglas's *cul-de-sac*, with a sponge electrode over the tumor on the outside. The current was kept up fifteen minutes. Six applications were employed. The size of the tumor was much diminished, and the tenderness and pain were lessened. The patient was now able to attend to her duties.

#### NEW INVESTIGATIONS ABOUT POISONING WITH JEQUIRITY.

We abstract from the *Ann. di Chim. e di Farm.*, No. 2, 1886, the following points of DR. BUFALINI'S researches on jequirity:

Jequirity, the seeds of *Abrus precatorius*, Lin., owes its powerfully toxic action to a principle soluble in water, which, introduced through the jugular vein directly into the heart, kills rabbits instantly through cardiac failure. Ingested by some other mode, death is not so rapid. In frogs, the drug causes at first cardiac arrest in diastole,—excitation of the cardiac inhibitory apparatus,—lasting seventeen minutes; later the beats of the heart appear again, the inhibitory apparatus becoming paralyzed. The drug produced in no animal any alterations of the pupils, and led Bufalini to believe that the distinct myosis observed in the course of the jequirity ophthalmia is merely a reflex effect of the keratitic process.

Finally, the observer states that the toxic principle of jequirity is probably identical with abrin, the glycoside found by Hardy,

Marden, and Waddel. Abrin foams strongly in water, and changes into glucose under the influence of a diluted acid.

#### THE LOCAL TREATMENT OF PSEUDO-MEMBRANOUS CROUP—INTUBATION OF THE LARYNX.

DR. J. LEWIS SMITH, in an article in the October number of *The American Journal of the Medical Sciences*, expresses his belief that intubation is destined to be employed more generally than tracheotomy in the treatment of pseudo-membranous croup. He maintains that in all cases in which the obstruction is limited to the larynx and trachea, intubation relieves the dyspnoea as quickly, effectually, and permanently as does tracheotomy. It gives, in most instances, complete relief for a time. If the respiration subsequently become embarrassed, and no benefit occur from cleaning the tube, tracheotomy may be required. Intubation may properly precede tracheotomy in most cases.

Not a few parents in the middle and lower classes allow their children to die rather than consent to this operation. On the other hand, few parents will object to intubation, and when they see the relief which it produces they will probably consent more readily to tracheotomy if the dyspnoea should return. If only one of these operations be performed, statistics thus far show nearly as good a result from intubation as from tracheotomy.

Now that diphtheria has become so common the physician should be provided with the necessary instruments for intubation whenever diphtheria appears in his locality. Alkaline and trypsin inhalations, properly and almost constantly used, and intubation performed early, when the patient begins to suffer from dyspnoea, would probably prevent the necessity of tracheotomy in a large proportion of instances. But if such treatment do not fully relieve the dyspnoea, it will in most instances so diminish it and retard the progress of croup that the physician, remote from help and unfavorably situated for the performance of tracheotomy, will have ample time to prepare for this operation. Intubation may prevent the need of tracheotomy, but if not, it presents no hindrance to it.

#### TREATMENT OF WHOOPING-COUGH.

The *Bull. de Thérapeutique* contains in its May issue a review of various modes of treating pertussis, which invites our interest.

As to the etiology of the disease, authorities like Michel and Hack agree that whooping-cough is a reflex neurosis originating in the nerves of the nose. These therapeutists, therefore, believe in treating the affection by means of powders applied to the nasal mucous membrane. Michel tested the rationale of this treatment in fifty cases, and pronounces the results obtained as satisfactory, in the majority of cases at least. The substances which he used in these cases were quinine, either pure or mixed with benzoic acid in the proportion of one of the former to three of the latter, tannin, boric acid, salicylic acid, iodoform, cocaine, bicarbonate of sodium, and marble-dust. The last-mentioned substance was used in order to study the action of inert powders. In several cases Michel ascribes the curative influence of the agents used simply to their mechanical action. The most effective substances which were tried were quinine, benzoic acid, tannin, and marble-dust; cocaine, salicylic acid, boric acid, and iodoform making very little impression upon the cough, the remedies being only used during the spasmodic phase of the disease. Of the fifty cases treated, all the symptoms of the disease disappeared at the end of eight days in six cases. In six other cases the symptoms were improved, but the duration of the disease was not affected. The weather exercised a marked influence upon the intensity of the disease, the cough becoming more painful and more frequent when it was cold and damp, especially if the wind were east. When the weather became milder and the easterly wind had subsided, the symptoms invariably improved. It was also observed that dampness had a more unfavorable effect than cold.

Sauerhering's plan of exhibiting quinine has been previously discussed in the GAZETTE. This physician professes to cure whooping-cough in from fifteen to twenty days with quinine alone. His doses are very large. To infants he gives 1 grain and more at a dose; to children in the second year of life,  $1\frac{3}{4}$  grains; and in the seventh and eighth, up to 4 grains. The quinine is given with a little sugar, one dose at night, and three doses on each of the following three days. Then there is a respite of three days, after which the same number of doses and in the same manner is to be repeated. The same plan is followed after three days more of rest, and by this time, in the author's experience, the cough has disappeared.\*

\* Henoch's experience with the method of Sauerhering was wholly negative.

Roger's treatment, when the paroxysms have a convulsive character, consists in the use of the syrup of valerian in doses of  $\frac{1}{2}$  to 1 fl. oz., or of the tincture of musk in doses of 5 to 10 drops for children under 2 years of age, and 10 to 20 drops for those between 2 and 5 years. If laryngeal spasms are frequent, he recommends the inhalation of emollient or narcotic vapors, burning in the vicinity of the nose and mouth nitre-paper, stramonium, or belladonna powder. When there are paroxysms of suffocation, he recommends (with Henoch) the inhalations of ether and chloroform. If suffocation seems imminent, he recommends the inhalation of ammonia, the free use of cold water upon the face, and active friction upon the walls of the chest, especially in the region of the heart.

Guerder, discussing likewise the therapeutics of whooping-cough in the *Journal de Médecine de Paris* (June, 1886), places a considerable stress upon thorough disinfection of the sick-room. In an extensive epidemic of pertussis, in February of this year, which was particularly prevalent among very young children, the author treated his cases, at first, by disinfecting the sick-rooms with carbolic acid, and then using a syrup composed of—

Syr. diacodii,  
Syr. belladonnæ,  $\mathbb{A}$   $\mathfrak{f}\text{ii}$ ;  
Acidi phenici, gtt. x;  
Potassii brom.,  $\mathfrak{f}\text{ji}$ .

This was administered in doses of a coffee-spoonful once or several times a day, according to the age of the patient. Only a moderate degree of success attended this treatment, and when the medicine was suspended the number of paroxysms became as great as before. The continued use of belladonna was also found very undesirable in young children, as it produced decided dilatation of the pupil, delirium, and a condition of narcosis which it was deemed prudent to remove.

The nasal catarrh which accompanied the disease, the injection of the nasal mucous membrane, and the probable parasitic character of the disease suggested the idea that the paroxysms of cough and asthma were of a reflex character, and might be susceptible to a similar course of treatment to that which has been found efficient in hay-fever. A powder was, therefore, made of equal parts of boric acid and of burnt coffee, and blown upon the nasal mucous membrane morning and evening. Thirty children were thus treated, seven being under 1 year of age, seven between 1 and 2, six between 2 and 3,

ten between 3 and 8. Seventeen of these received almost no treatment except the insufflations, while the others had already received some benefit from the use of the syrup, the formula of which is stated above. In all cases benefit began to be apparent in from two to six days, the paroxysms of coughing becoming less frequent and less intense, the vomiting, the epistaxis, and the nasal catarrh diminishing or disappearing. The general condition also improved, and in fifteen to twenty days the patients were apparently well. This result is the more satisfactory since the cases occurred among poor people surrounded by bad hygienic conditions, and the children were out of doors much of the time in cold and wet weather alike. In those cases in which the insufflations were practised at the beginning of the disease, the course was invariably a mild one, and a cure was effected in eight to fifteen days. Powdered benzoin, which was recently recommended by Michael, of Hamburg, for this disease, to be used also by insufflation, gave good success, but was not so satisfactory as the mixture of pulverized boric acid and pulverized roasted coffee.

In conclusion, we allude to the treatment of Dr. J. Bachem, of Bonn, who blows a mixture of muriate of quinine (three parts) and powdered acacia (one part) in the nostrils once or twice daily. In sixteen cases thus treated he effected a cure after an average treatment of twenty-one days.

Our readers will recall from the therapeutic notes of our special correspondent at Berlin that Henoch regards opium as the only reliable remedial agent in whooping-cough.

#### NOTHNAGEL ON THE TREATMENT OF PERICARDITIS.

PROFESSOR NOTHNAGEL, of Vienna, in a clinical lecture on the treatment of pericarditis, advises that in cases where there is pain in the cardiac region, fever, and the commencement of exudation, leeches, varying in number from three to ten, according to the gravity of the symptoms and the constitution and strength of the patient, should be applied. The leeches should be renewed every four or six days. Cupping may be substituted, but leeches are preferable. An ice-bag should be applied, or a directing apparatus through which cold water can be constantly supplied to the part. Cold compresses are of no use unless they are laid on ice, and then they must be changed every five minutes.

Digitalis for internal use is indicated under certain circumstances. It is useful if the cardiac action is greatly increased, especially if there are signs of the heart-muscle becoming implicated, when it should be given in somewhat larger doses. Digitalis is not desirable in the earlier stages of the disease, but in the later ones, when there are signs of weakness of the heart-muscle and the pulse is weak, it is indispensable. Other internal remedies are useless. Mercurialization—viz., calomel in small doses of three-quarters of a grain internally, and gray ointment externally—has no effect. The pain is scarcely ever severe, and if it is persistent it may be relieved by cold and blood-letting. To this a high temperature is no drawback, as the fever subsides as the inflammatory appearances disappear. If effusion has begun, other means must be used, such as counter-irritation of the skin and the promotion of reabsorption. Ice and blood-letting are of no use in this case. The cardiac region must be painted with equal parts of gall and iodine tincture, or an ordinary cantharides plaster may be applied, which should be kept on from eight to twelve hours till a blister is raised. This is of greater use in subacute than in acute pericarditis. Digitalis does not directly promote reabsorption, but indirectly by its influence on the action of the heart. Should the patient's life be threatened by copious effusion, paracentesis of the pericardium must be performed. This operation is often employed, and with not unfavorable results. Great care must be observed; the pointed trocar of Dieulafoy's apparatus must not be used, but a blunt one, like that of Dr. Fraentzel.—*Lancet*, September 4, 1886.

#### PROPAGATION OF MEASLES BY HEALTHY PERSONS.

From an editorial of *Le Concours Médical*, June 12, 1886, we abstract the following observations:

The possibility of carrying the contagious principle of measles from place to place by the medium of the bodies of healthy persons was recently discussed by the Medical Society of Berlin, and one gentleman, Joel, of Lausanne, presented certain facts, which lead to the belief that such a possibility does exist, and that the medium is often furnished by the physicians themselves. One case which was cited was that of a boy who was brought from Geneva to Lausanne while he was passing through the incubation stages of measles. The butcher and the postman who served the

institution to which the boy was brought conveyed the disease to their children, who were attacked with it in a short space of time, and, what is quite remarkable, the children in almost every house to which the postman delivered letters were attacked. A little girl was brought to a hospital, and in a few days had undoubted symptoms of measles. Her father had paid her several visits before the measles appeared, and it was ascertained that two of his children were suffering at his home from the disease. Eight other children in the hospital were quickly seized with it.

It is thought that physicians cannot always avoid carrying the contagion with them, even when extraordinary care is taken. Prophylactic means on the part of the physician should be as thorough as possible, however, by disinfection, change of garments, and all other available procedures.

**RHEUMATISM: ITS NATURE, ITS PATHOLOGY, AND ITS SUCCESSFUL TREATMENT.** By T. G. MacLagan, M.D. New York: William Wood & Co., 1886.

Those who are familiar with Dr. MacLagan's earlier work on rheumatism will read this volume with increased interest. Ever since 1876 an advocate of salicin, he now uses the salicyl compounds with almost equal success, though still retaining his original idea of the superior virtues of the former. With his belief in the miasmatic or malarial nature of acute rheumatism any one may differ, but of the value of the salicyl compounds nearly all are satisfied who have employed them to any extent. The author's description of the varieties of rheumatism may challenge the opposition of many. Certainly there is room for doubting at least the dogmatic statement of his first page, where, dividing the disease into acute, subacute, and chronic, he says, "The three forms have originally the same causation." For in order that this should be even superficially true the name "chronic rheumatism" should be strictly limited to those cases which have been originally acute, where the chronic condition has been evidently brought about by a single or repeated acute attack, while the so-called subacute variety is a convenient refuge for other forms of joint trouble and constitutional trouble by no means always clearly rheumatic. Now we believe firmly that there is a rheumatism and that there is a gout, the two diseases dif-

fering entirely in the circumstances of their causation and in their effects on the human organism; and we find that Dr. MacLagan at the outset, in describing and defining the varieties of rheumatism, says, "Chronic rheumatism properly so called is a milder form of the subacute variety,"—thereby defining a chronic rheumatism quite unlike that generally described. In fact, chronic rheumatism, according to the author, "is sometimes the precursor . . . of an acute attack,"—"chronic thickening of the fibrous textures involved in the disease." "A sequence of rheumatism" is a condition which exists, when once established, "independently of the rheumatic poison," and is by no means, the author wishes us to understand, chronic rheumatism at all.

Of the duration of the disease the author has necessarily much to say; he places its ordinary term at two or three weeks. The prolonged cases are explained as "those in which the chronic form of the disease follows in the wake of the acute." This, while ingenious, by no means clears up the case, since in such a view we are required to consider the subacute and chronic forms as separate diseases, complicating, invading, and temporarily occupying the unfortunate subject, while we have already been told that they were one and the same disease, produced by the same cause,—that the subacute was only a milder form of the acute, and the chronic often the mildest of all. Yet the author speaks of "this grafting of the chronic on the acute form." In the light of the author's subsequent remarks on the treatment by salicin and salicylic acid this becomes a matter of some interest. Were it not for that, it might be passed over as only a loose method of description.

Of the seat of this disorder the author entertains decided views. It is "not the fibrous tissues generally, but the fibro-serous tissue of the motor apparatus of the body," and "rheumatism is essentially a disease of the motor apparatus." To support this he points to the immunity enjoyed by the periosteum and the dura mater, the fibrous tissue of the liver, spleen, and kidney, the general freedom from attack possessed by the small joints, the articulation of the jaws and ribs, of the atlas and axis. He "never saw or heard of a case in which the articulations of the ribs were involved." All such cases were, of course, gout.

Of the clinical fact that overstrain and fatigue of a part exercise considerable power in a rheumatic attack in determining the loca-

tion of the disease he makes considerable use. "The only internal organ which is habitually the seat of rheumatic inflammation is also the only one whose fibrous textures are habitually subject to strain." The author very properly deems that exposure to damp and cold suffices to produce acute rheumatism. Such exposure, if sufficiently prolonged, may produce gout of a chronic form; but none the less is the author at fault when he says if such were the case it should be "most prevalent in the coldest climate and the coldest weather," for he forgets that extreme cold is dry and dampness is one of his theoretical factors of causation. Any conclusions drawn from the hereditary nature of rheumatism should be closely scrutinized; from the view of an essential contagion or miasm of the disease they tell against it somewhat, as in the case of tubercle, where we must suppose the susceptibility rather than the poison itself to be inherited. The actual fact itself is in dispute. Is acute rheumatism hereditary, or is a certain weakness and vulnerability only of the fibrous tissues hereditary? Do children whose parents were subject to acute rheumatism have it because they, equally with their parents, have suffered from local conditions of cold, dampness, and miasm? The author admits (p. 19) that "the liability to repeated attacks in the same individual equally points to a constitutional predisposition rather than to an external and accidental agency," yet draws from the special characteristics of the disease the conclusion that it is specific and "the result of the action of a special poison."

Special blood poisons the author divides into those which are produced within the system and those which enter from without. He gives us an exhaustive examination of the lactic acid theory, which he demolishes to his own satisfaction. While quoting the experiments of Richardson on the induction of heart lesions by injection of lactic acid, and arguing against their conclusiveness, he fails to mark one cause of doubt which the reviewer witnessed some years ago in a series of similar experiments, where undoubted valvular lesions were found in the dogs injected, but where similar lesions were also found in a second series of dogs killed without experiment and in a condition of apparent health. Dr. MacLagan, however, holds so firmly the miasmatic theory that defects in his own chain of reasoning are of little moment to him. From conditions obviously pointing one way he readily draws a conclusion in the opposite direction.

The lactic acid theory being rejected, the author proceeds to argue for the miasmatic theory. The natural history of rheumatism allies it closely, he thinks, to malarial fevers. Its habitat is similar, its fever is irregular in type; it is, like malaria, uncertain in duration, unless checked by remedies; yet the poison is not the same. Still, he marks the division in rheumatism of two kinds,—intermittent and remittent,—and having established the relationship he gives us an elaborate study of malaria, its nature, and mode of action; and in Chapter X. we read in the opening line, "Acute rheumatism we regard as a form of malarial fever."

In studying the disease the author makes an arbitrary division into rheumatism of the locomotor apparatus and rheumatism of the vasculo-motor apparatus. In these two chapters and the succeeding one on endocarditis, pericarditis, and myocarditis one will find many facts concerning the disease which are generally overlooked, many facts placed in a new and ingenious relationship, and many statements which may challenge dissent from most readers. Read in the light of the most recent views on ulcerative endocarditis, the three last chapters are extremely interesting, though by no means so in the way the author intended.

The author professes to have been led to the use of salicin, with which his name is closely connected, by a study of the plants of low-lying, damp, and rheumatic neighborhoods. As willows and rheumatism both love the water-courses, so, by an easy argument, salicin hates rheumatism; and though the salicylates have almost overpowered the genuine alkaloid, Dr. MacLagan is still faithful to its fortunes, believing it superior in efficacy and safety to its more palatable and cheaper competitors. In the use of his favorite remedy he shows no timidity. "It takes about an ounce of salicin or salicylic acid to remove the acute symptoms. That quantity should be taken within the first sixteen or twenty-four hours." Forty grains every hour is his favorite dose until the acute symptoms begin to yield, then another ounce is administered during the next forty-eight hours, and so on in diminishing quantity, and continued some days after all symptoms of the disease have subsided. Of salicin he says, "It may be gone on with for some time without hesitation, . . . and those treated by it convalesce more quickly than those who take salicylic acid."

In some of the author's recorded cases he reinforces the salicin by bicarbonate of potas-

sium, alone or with potassium iodide. The reason of this he explains by a necessity in some cases for neutralizing the acid (lactic) in the blood and fibrous tissues, while the salicin attacks and destroys the miasm or specific poison of the disease.

In the chapter on "the mode of action of the salicyl compounds in rheumatism" the reader may follow the author's ingenious reasoning, and agree with him if he chooses; but aside from any theory as to its action, we believe that the majority of the profession thoroughly support Dr. Maclagan in the use of the salicylates, and that where dissatisfaction is expressed with the results of this treatment it is because the practitioner has used too small doses from a dread of depression. As to salicin, while its bitterness is a drawback, it is much better borne by the stomach than the mawkish salicylates, and seems to possess certain powers foreign to them. It can undoubtedly arrest the neuralgic pain, which forms the principal source of suffering in many cases. In thoracic rheumatism it acts more certainly and rapidly, and in the case of children its use is freer from that slight suspicion of danger which will intrude in using large doses of the salicylates. We see, in going through the book, no mention of that most valuable salicylate, the salicylate of ammonium,—a salt which theoretically meets any objections urged against the others, and which is less likely to nauseate. It can be prepared extemporaneously by adding in solution fifty grains of ammonium carbonate to sixty of salicylic acid, and has a purely sweet taste and a syrupy consistence.

Ever since the issue of Dr. Maclagan's early paper some ten years ago the reviewer has employed salicin wherever indicated, and is disposed to think as highly of its virtues as does its original discoverer, and it seems to him probable that it may also be useful in other fields than those rheumatic. As a tonic it is decided in its action, as a febrifuge or antipyretic it possesses considerable power, and in obscure malarial attacks it seems to add new force to quinine by its combination. In the vague depression, dull spinal pain, frequent headaches, and general malaise so often brought back to the city from summer sojourn and travel, where quinine fails it will be found often useful, and, although originally an expensive salt, its price is now so low as to render its use in the necessarily large doses feasible everywhere.

The author by no means assents to the view that salicin is converted in the system into

salicylic acid; he considers that it is much more probably converted into saligenin, salivetin, and salicylous acid. This is a very nice point and one upon which opinions may differ; we have none. In the matter of relative safety, however, the author's words are of weight. He asserts that salicin may be freely administered to a system depressed by the toxic effects of salicylic acid, and that under its use the toxic effects and rheumatic symptoms disappear together. Upon neither the brain nor heart has he observed it to act unfavorably. These are valuable points. The remainder of his book is occupied by chapters on the treatment of vascular motor rheumatism, the relation of rheumatism and chorea, cerebral rheumatism and rheumatic hyperpyrexia; and the book, as a whole, forms a treatise on this subject,—original, bright, erratic at times, but of great value, whether the reader coincides with or combats the author's peculiar theories. E. W. W.

A TREATISE ON ELECTROLYSIS AND ITS APPLICATION TO THERAPEUTICAL AND SURGICAL TREATMENT IN DISEASE. By Robert Amory, A.M., M.D., etc.  
New York: William Wood & Co., 1886.

This is a well-timed book, and deserves the attention of those who are interested in the scientific progress of electricity in medicine and surgery. It reflects, and is no doubt inspired by, the revived interest which is now being taken in this department of therapeutics, and which is, perhaps, the most rational and healthful that has ever characterized it since physicians first applied electricity to the cure of disease. This reformation (if we may so call it) is no doubt partly due to the great development of both the science and art of electricity in the commercial world. The mercantile spirit has given a stimulus to the thorough investigation of the physical and chemical qualities of electricity, and has also devised methods of producing, handling, applying, and measuring it, which have much increased and systematized our knowledge of what can and cannot be accomplished with this subtle agent. Those persons who had the opportunity to visit the Electrical Exhibition in Philadelphia in 1884, and to critically analyze its best features, could not but be struck with the truth of these observations. They must have recognized that the time had come when it was just as necessary, and almost as easy, for the physician to be exact in his methods, and precise in his results, with electricity as in the cases of any other experimenters and workers with it.

It is true that Dr. Amory has taken up one of the most obscure and involved questions of electro-therapeutics, but one which is probably the very foundation of the science. It is doubtful, indeed, whether the time has come when this subject can be treated in books with more than a small profit. This opinion is confirmed by this book. The subject must be more thoroughly worked upon in the laboratory and the clinic before it can be finished up in the study. The book has the merit, however, of laying out the ground and of reviewing the literature of the subject, while it labors at a disadvantage under a great weight of physiological speculation and many tedious reports of cases.

Electrolysis, as our readers know, is the decomposition of fluids, and substances dissolved in them, by the passage through them of an electric current. It depends upon the polar affinity of the elements forming the fluid, the negative elements seeking the positive pole and the positive elements going to the negative. The decomposition of water is the most familiar example of electrolysis, and may be observed by any one having a galvanic battery. In this the hydrogen seeks the negative pole and the oxygen seeks the positive. This decomposition can be accurately measured, and is in exact proportion to the strength and duration of the current. Thus, for every *coulomb* of electricity there will be evolved 0.1764 c.c. of the mixed hydrogen and oxygen gases. If any simple salt is dissolved in the water, it, too, is decomposed, and the acid collects at the positive pole, while the alkaline base flies to the negative. These acids and alkalis, being thus separated, may, in turn, exert their special chemical actions, and this is what is called the *secondary* action in electrolysis. Thus, in the human body, electrolysis having collected certain acids at the positive pole, these acids would exert their power upon the tissues. It is easy to understand that the more complex the fluids submitted to this process the more complex will be the respective accumulations at the two poles, and the more involved will be the secondary chemical actions and reactions of these accumulations, or *ions*, as they are called. It is right at this point, and because of this complexity, that much obscurity rests upon the subject of electrolysis in the human body. These highly organized tissues, constantly changing in the vicissitudes of health and disease, never exactly alike, often inaccessible to our means of inspection, furnish a problem infinitely more complicated than

simple saline solutions, which can be reproduced at will, and excite the inquiry whether, after all, our procedures must not for a long while remain empirical, and our results be clinical rather than experimental. This has been the fate of many other therapeutic agents.

These elementary facts of electrolysis have, of course, been known for many years, and physicians long ago sought to avail themselves of them. It is one of the merits of Dr. Amory's book (shared to a like extent by no other book in the English language that we know of) that it gives us much information about these attempts. But Dr. Amory does not confine the use of the word electrolysis to the decomposing process above mentioned. In fact, he does not believe that this process can account for many of the clinical facts with which we are acquainted. He believes that the *cataphoric* action of the current, or, as he calls it, electrical *osmosis*, is the cause of many of these effects. He illustrates this as follows: "If two platinum electrodes should be connected with a constant galvanic current from ten or twelve cells, and then be immersed in pure water, the negative or zinc terminal within a porous vessel, and the positive or carbon terminal outside of this porous medium, the water in the inner vessel will accumulate in two hours to a level about one-sixth higher than that in the outside" (p. 291). In other words, there is a flow of the fluid through a porous septum from the positive towards the negative pole. Dr. Amory makes this one physical fact the basis for a vast amount of speculation, which is both wearisome and profitless. He offers few, if any, facts or experimental observations of his own or others to enforce his various theories, but relies very much upon badly-reported cases, which he has collected from authors, some of whom have been very much discredited. This seems to us to be the most serious fault in the book. It becomes in parts as occult and speculative as any electropath could wish, and is, moreover, drawn out with a wordy tedium which we often wish had been spared. The author, for an example, believes that the segmentation and proliferation of protoplasmic cells can be influenced by this process, for, he says, "It is not only that electricity may transport fluid particles *en masse* from the positive to the negative electrode; but this transportation of fluids may induce organic changes by the rapid removal of the pabulum upon which these cells depend for their maintenance and propagation" (p. 290). This may

or may not be true ; but it certainly needs not so many closely-printed pages to develop an idea which the author himself introduces as a *may-be*. This biological speculation, on the one hand, and the haphazard application of the current (without measurement, without exact observation and unbiased reports), on the other hand, as in most of the cases in this book, cannot impart to our electro-therapeutics either the dignity of a science or the usefulness of an art. There is truth in both electrolysis and osmosis, and experimental observations, it is hoped, will yet make us much better acquainted with them. In the mean time clinical work may follow such indications as these processes can now give us, and especially report accurately both methods and results. The cases which are compiled in Dr. Amory's book—many of them, at least—seem to us to be so meagrely and badly reported, and with so much prejudice, as to be quite useless. What experimental therapist would think of reporting his results with a new drug, and at the same time omit to mention the dose and about one-half of the details? And yet this is an almost universal fault with electro-therapeutists. The author's own cases of goitre, treated by galvano-puncture, are decidedly the best and most instructive in the book. We wish he had relied more upon his own observations in other diseases.

This treatise, in spite of the faults which have been mentioned, appears to us to be both useful and suggestive in a number of ways ; and, in order to do it perfect justice, as well as to do the reader a service, we will briefly indicate its contents. The first half of the book, or about one hundred and forty-seven pages, is devoted to the theory of the subject. The physical relations of electrolysis and electrical osmosis are given, and the authorities on these abstruse subjects are referred to in sufficient detail. The various forms of batteries are mentioned in about the same manner as in our better text-books on medical electricity. The author uses the word *tension* very often, and in a way that is sometimes confusing. We thought that this word had about seen its last days. We can understand *current-strength* and *quantity*, which are the facts which regulate electrolysis and all other applications of electricity to the human body, but *tension* in electro-therapeutics has become as dubious a term as *high potencies* in another branch of therapeutics. About twenty-five pages are devoted to a theory of the destruction of living tissues by elec-

trollysis, of which we have given our impression above. It all remains to be demonstrated. A chapter upon the methods of employing electrolysis in living tissues is practical and good. The last half of the book is devoted to certain diseases in which electrolysis has been practised, and draws largely upon the experience of those who have made clinical trials of the method, and who are in general best known for their efforts. A table of reported cases has value chiefly as an index. It is too like a skeleton for any one to taste of the meat. We have, however, much from Cinicelli, who has made valuable studies of electrolysis in aneurism, and many other references, which give this book marked literary value. The reader will be interested to read of the cure of a leucoma by galvano-puncture with a delicate needle, and amused to read of another case of the same disease in which, instead of the needle, a *wet sponge* was held over the *closed eye*, and, of course, no cure was obtained. These two cases illustrate the rational practice, which is rare, and the haphazard practice, which is common, in the use of electricity. The author reviews the subject of electrolysis in ovarian tumor, which was heralded some years since as about to abolish ovariectomy, and appears to give more credence to Ehrenstein than would be expected. Ehrenstein claimed to have cured several hundred cases of abdominal tumors, but never gave any particulars that could be relied upon, and was proved by Dr. Mundé to be a visionary.\* Dr. Amory thinks that electrical osmosis here plays its part. Sceptics have said that the tumors are reduced by oozing from the punctures. Among many other diseases treated are hydrocele, nævus, and cancer. Some of these cases are undoubted cures, and therefore very valuable. The use of electricity in the hyperplasias of the female pelvis, and in stricture of the male urethra, has not received the notice it requires. Exophthalmic goitre receives a great deal of attention from Dr. Amory, and it is exceedingly irksome to have to read, in such a work as this, *twenty-nine* closely-printed pages of the pathology and symptoms of the disease before we come to the practice. Whatever his theory may merit, it is certain that some of the results obtained by him are very striking and worthy of imitation. Hypertrichosis, or supernumerary and abnormal hairs, and their removal by electrolysis, receives the attention which the

\* Transactions of the American Gynæcological Association, 1877.

subject deserves in a very complete chapter. One of the closing chapters is devoted to measurements of the current-strength, and testifies to the author's zeal as a scientist. Apparatus is well described, and a general summary brings the work to a close. We may say, by way of final criticism, that the book could have been much more concisely written, and that the whole subject must be more thoroughly established by practice and observation; but, also, that Dr. Amory has rendered a genuine service to those who interest themselves in the use of electricity in disease.

J. H. L.

THE MEDICAL DIGEST, OR BUSY PRACTITIONER'S VADE MECUM: BEING A MEANS OF READILY ACQUIRING INFORMATION UPON THE PRINCIPAL CONTRIBUTIONS TO MEDICAL SCIENCE DURING THE LAST THIRTY-FIVE YEARS. By Richard Neale, M.D. London, etc. Second Edition.

London: Ledger, Smith & Co., St. Mary Axe.

The publishers of Neale's "Digest," desirous of an expression of opinion as to the advisability of issuing an appendix every fifth year, call attention to the subject by a leaflet accompanying the work, the heading of which, "How to Use the 'Digest,'" indicates its purpose. In it the author again protests against the idea that the book is "merely an index" to certain specified journals, and contends that it is far more, a true digest, from whose pages, by a little trouble, the practitioner, without access to the journals referred to, can yet gather an immense amount of valuable information and useful suggestions on any topic that occurs to him. That this claim is true a very little study of the book in the lines indicated by the leaflet will convince any one, for as each reference leads to others, the very titles of the articles give new ideas on the subject.

But we should judge that this use of the book was altogether inferior to the evident use of it as an index after all. As a means of reference to all important medical journal literature in the last thirty-five years it is to the student and writer invaluable, and to the occasional writer still more so. In fact, it is only by means of such a book that elaborate and studied articles can be written, and the issue of another appendix in 1887 will be hailed with joy by thousands of students and writers. The journals which have contributed to form this book, and to research in which the book contributes, are the *Am. Jour. Med. Sci.*, *Braithwaite*, *British Medical*, *Lancet*, *Med. Press and Circular*, *British and For. Med.-Chir. Rev.*, *London Med. Gaz.*, "Royal London Ophthal.

*Hosp. Rep.*," *Ranking's Abstracts*, *London Med. Rec.*, *Med. Times and Gazette*, *Practitioner*, *Edinburgh Journal*, and a number of standard books besides.

## Correspondence.

### BICHLORIDE OF MERCURY IN UTERINE CATARRH.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Since January last I have been using a solution of bichloride of mercury as an application to the cervical canal and uterine cavity in cases of chronic mucopurulent discharge. Originally it was suggested to my mind by some considerable success with the same agent in gonorrhœa, as recently recommended. The suspected relation between many chronic inflammatory conditions of the female genital organs and gonorrhœa still further suggested the use of the bichloride, though in much stronger solution.  $\frac{1}{2}$  to 1 grain to the ounce of water was the strength I employed, and, on trying it, my success was so much better than ever before that I have continued to use it in all possible cases of the kind. It has several manifest advantages. Applied with the cotton-wrapped applicator, it excites no immediate uterine contraction, as iodine, carbolic acid, and other agents generally do. This enables one to make two, three, or more applications in rapid succession, and affords a much better chance for reaching the entire endometrium. It leaves behind it no coagulated mucus, or film of chemically-altered epithelium, as carbolic acid and nitrate of silver do, to be detached and expelled subsequently by a process almost necessarily involving fresh supuration. A similar solution may, as a final measure, be applied to the whole vaginal membrane as the speculum is withdrawn, and irrigation with hot water or a very weak solution of bichloride continued for some days. In obstinate catarrh of the cervix, with almost endless ropy secretion, I have also had good success, while I do not remember, after many trials, any success worth mentioning with any agent employed previously. In nearly all the cases two or three applications entirely checked discharges of long standing. Sometimes they recurred at the monthlies, but were again checked for good apparently by another application. In two cases single applications did the work, and out of the twenty-three cases treated solely in

this way, two only resisted treatment, and were entire failures.

*IS IT SAFE TO GIVE PEPSIN PREPARATIONS WHEN LESIONS OF THE MUCOUS MEMBRANE EXIST?*

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—At the time I read the article on pepsin in the September number of the THERAPEUTIC GAZETTE, I was treating what I and my consulting physician considered to be a case of septicæmia following on a dysentery, in which pepsin had been used. This case I will briefly state.

The man was in his prime, temperate, industrious. He came down with dysentery, which yielded in ten or twelve days, with no very extraordinary symptoms. His pulse and temperature subsided, and appetite, with normal discharges, returned. During the last of his sickness preparations of milk and of egg were frequently given in connection with "dyspepsin," with no thought of any danger. When convalescence was so satisfactory, and every symptom favorable for a speedy recovery, on the fourteenth day he was suddenly taken worse,—a chill, pulse 125, temperature 104°, pain in neck, with rapidly increasing purple swelling in left parotid and the surrounding tissues. To this swelling tincture of iodine was applied and proved advantageous in relieving and reducing the swelling, though not wholly saving from suppuration. An active diarrhœa began with the relapse, and continued till the last, hypodermic doses of morphine and belladonna alone seeming to be of any benefit. After three or four days there were some symptoms of peritonitis, though not strongly marked. The mind remained clear, with slight exceptions, till the last, when death took place, twenty-one days from the beginning of the sickness, or seven days after relapse.

What was the matter? Why this set-back, or, rather, this new series of symptoms? He was so carefully watched and treated we know of nothing, unless the pepsin had entered the circulation through the ulcerated bowels and poisoned the blood. Of this I had no idea till I read Dr. Wood's article. Is it possible pepsin is dangerous when conditions exist favorable to its absorption into the circulation? If so, we have a hint to the possible cause of the frequent cases of blood-poisoning in the modern wholesale use of the digestive fer-

ments. It is, indeed, time that the whole subject of these ferments was gone over and the danger pointed out, if danger there be, and the line of demarcation sharply drawn between the cases when their use is safe and when it is not.

At this writing I have a case of typhoid fever, where, a few weeks ago, I should have resorted to pepsin in some form, but now I dare not give it. If pepsin is poisonous to the blood, then it must be regarded dangerous in any case where there is lesion in any part of the alimentary tract over which it may pass and be absorbed.

Notes and Queries.

---

*SQUILL A POISON.*

The death in March last of two young children from large doses of a cough mixture containing syrup of squill called attention to the danger attendant on the unrestricted use of this popular cough remedy. A long paper in the last two numbers of the *Lancet* by Dr. E. B. TRUMAN, F.C.S., public analyst for the borough of Nottingham, detailing the results of his examination of the mixture which was used and some other experiments, recalls the circumstances of the case. The mixture which was used contained almond oil, 2 drachms; syrup of violets, 4½ drachms; ipecacuanha wine, 1½ drachms; and syrup of squill, 1 ounce. It caused pains in the legs, a livid appearance of the face, and quick respiration, followed in two cases by death. The post-mortem examination showed that the heart had ceased in systole, a phenomenon which only results in the case of three officinal drugs, viz., digitalis, squill, and green hellebore. The supposition was that digitalis had accidentally been dispensed in place of one of the ingredients of the mixture, and Dr. Truman was asked to make a chemical examination of the remaining portion of the mixture. He did so, but found no indication of the presence of digitalis, and subsequent experiments with syrup of squill, and other ingredients of the mixture, procured from the pharmacist who dispensed it, pointed to squill as being the toxic agent. Samples of the syrup were obtained from other sources, and these, along with the first syrup, ipecacuanha wine, tinctures of digitalis, and green hellebore and digitaline, were used in physiological experi-

ments upon the heart of the frog. The result of the experiments shows that while the glucosidal residue from 30 minims of the fatal syrup of squill caused cessation of the heart's action in thirty-eight minutes, a similar quantity of another sample reduced the beats from thirty to ten in forty-seven minutes, and another had scarcely any action at all. Ten minims of tincture of digitalis reduced the number of beats from thirty-nine to eighteen in twenty minutes, and 110 minims of tr. verat. virid. reduced the number from fourteen to six in twenty-five minutes. A proportionate quantity of the fatal mixture also caused cessation of the heart's action. There was no doubt, therefore, that squill was the toxic ingredient of the mixture, and this is the conclusion that Dr. Truman arrived at. The syrup used in this instance had an intense and persistent bitter taste, like that of scil-litoxine, the glucoside of squill which arrests the heart's action in systole. From his experiments, Dr. Truman concludes that squill varies in strength, as the different effects of the three syrups show. The outer scales are stronger than the inner, because they contain more scillain; the fresh bulb is stronger than the dried, volatile oil and Landerer's extractive being lost in drying; the bulb gathered in summer is stronger than that gathered in autumn,—in summer the squill contains less sugar, and the increase of sugar in the autumn is probably the result of decomposition of the glucosides; the red variety is stronger than the white. Dr. Truman is also of opinion (1) that squill is not a safe drug to use for routine, and especially popular or lay practice; (2) that being so variable and, when strong, so potent a drug, it should be looked upon by the profession as unsuitable for use until a solution of standard strength can be produced; and (3) that in the mean while its use should be discontinued. These conclusions, although apparently justified by the facts of the case, cannot be accepted straight off. Dr. Truman has undoubtedly done good service in going into the matter so thoroughly, but there are several moot points remaining. The squill which was used for preparing the syrup was not forthcoming, and we cannot therefore say whether it was exceptionally toxic or whether the preparation was improperly made. Moreover, although the pink variety of squill is admitted by the Pharmacopœia, we do not recollect having ever seen it in commerce; certainly it is so uncommon that pharmacists would not use it if it were supplied to them. We are at one

with Dr. Truman on other pharmacological points, and trust that some competent pharmacist will make a thorough chemical examination of the squills of commerce, and determine, if possible, a simple means of ascertaining its strength. An isolated case of poisoning does not justify the proposed discontinuance of the drug, but the caution is necessary for mothers who give their children half-teaspoonful and teaspoonful doses of the syrup when a few drops would act sufficiently as an expectorant. If there were a much weaker syrup—for example, one containing an ounce or two ounces of acetum scillæ in a pint of simple syrup—the likelihood of fatal cases occurring would be very small indeed.—*Chemist and Druggist*, September 11, 1886.

#### ON RHEUMATISM.

IMMERMANN'S remarks about rheumatism were attentively listened to at the Berlin Congress, though no new features of an etiological or therapeutical nature were presented. The well-known fact of the frequency of the affection in one and the same house was again referred to. Immermann questioned whether cold is productive of rheumatism.

#### THE REMOTE EFFECTS OF REMEDIES.

At the meeting of the Medical Section of the British Medical Association, the President, DR. BROADBENT, selected for the subject of his address the Remote Effects of Remedies. After referring to the well-known after-effects of alcohol, he alluded to the mental and bodily derangement induced by eating opium, the miserable irresolution and wretchedness of the man who habitually resorts to chloral, and the childish dementia brought on by the prolonged use of the bromides. He thought that coca is already beginning to claim its victims, who gradually develop an excitement which becomes maniacal or an exaltation like that of general paralysis. The subject of gout was given as illustrating the remote effect of remedies. The effect produced by continued and excessive use of colchicum and other drugs having a similar action, and the consequences following the neglect of such treatment which will clear the system of the gout poison, were especially drawn attention to. With reference to the latter he urged: "It can scarcely be too often repeated that all the effects upon the arteries on the one hand and

the heart on the other associated with contracted granular kidney,—viz., arterial degeneration, cerebral hemorrhage, aneurism and dilatation of the left ventricle, and valvular disease,—are just as commonly produced independently of kidney-disease by high pressure in the arterial system due to other causes; and such pressure in an extreme degree may be induced prematurely by the means taken to keep down gout." Another cause of injuriously high arterial tension was the "Banting" treatment of obesity as understood by the public. In this the non-nitrogenous sugars and starches were taken very sparingly, the amount of fluid taken into the system was reduced as much as possible, and the subject lived on a highly nitrogenous diet. The imperfectly oxidized nitrogenized waste present in the blood provoked resistance in the capillaries, and generated tension in the arteries. Exercise and an adequate supply of water, which were generally omitted, were essential to active metabolism and the working off of impurities. Another example of injury given was that furnished in asthma. Certain drugs afford alleviation of symptoms, but many popular powders contain powerful alkaloids, which produce after-effects on the nervous and vascular systems. "When we see the stupefied mental condition and the congested face and eyes, and note the large, weak, sluggish pulse, showing paralysis of the arterial walls, it is clear that such effects cannot be indefinitely repeated with impunity." "The right ventricle loses its tone like the muscular coats of the arteries, and, instead of becoming hypertrophied, yields to the resistance in the pulmonary circulation, and is dilated, finally giving rise to systemic venous stasis and dropsy." A striking illustration of his subject was given by the too careful and restricted diet of certain forms of so-called indigestion. One kind of food after another was left off, but still with the same discomfort and a sense of repletion after food. The appetite being wanting, a starvation point becomes almost reached. Instances of severe neuralgia, spurious attacks of angina pectoris, and serious debility were related as having followed this line of treatment. Again, in the winter indigestion of women and weakly men, the functional energy of the stomach required stimulating by extra food, such as beef-tea, egg-flip, stimulants at meals, and tonics. What was wanted in winter indigestion was protection from the depressing influence of cold or the means of neutralizing it.—*Lancet*, August 21, 1886.

#### IS PETROLEUM POISONOUS?

The *Archiv de Pharmacie*, No. 3, 1886, gives the following description of a case of poisoning with petroleum:

A woman took with suicidal intent half a pint of petroleum. Soon after ingestion of the substance she experienced a burning sensation in throat and stomach, and complained of intense thirst. She received milk and cold applications to her head. The urine showed during the first four days evidences of being mixed with petroleum, which partly appeared at the surface and partly in a state of an emulsion. On the fifth day no more petroleum was discharged by the urine. The urinary sediment contained numerous epithelial cells, cylinders, and oxalate of lime; a small amount of albumen was also present. In five more days the urine was wholly normal.

The rapid elimination of the petroleum, and the quick disappearance of all morbid symptoms of the case, induce Dr. CHOAY, under whose observation the case came, to declare that petroleum is not a poisonous agent.

If there were no other instances of petroleum intoxication recorded in medical literature, we think the presence of cylinders and of albumen to be sufficient evidences for the toxic nature of petroleum.

#### AN IMPROMPTU STOMACH-PUMP.

DR. CHARLES N. DIXON JONES, of Brooklyn, writes to the *Medical Record*, October 16, 1886, as follows: "Apropos of the article on 'An Impromptu Pump for Stomach Irrigation,' by Dr. S. E. Post, allow me to relate the following instance of inventive ingenuity. About four months ago I provided a patient, suffering with gastric catarrh and dilatation, with the simple siphon apparatus and a cocaine solution, for stomach irrigation. From experience he found that the siphon did not at all times act as satisfactorily as was desirable, so he resorted to the following modification: He obtained a three-way stop-cock, made from gas-pipe. To one limb of the stop-cock he attached the stomach-tube; to the opposite limb a large fountain-syringe was attached by means of rubber tubing; the outlet was connected with a rubber tube, to the extremity of which could be attached a large rubber-bag syringe, such as is commonly used for a flower-sprinkler. The apparatus is worked as follows: The stomach-tube is in-

roduced, and then the stop-cock so manipulated as to allow the fluid to flow directly from the fountain-syringe into the stomach. After sufficient fluid has flowed into the stomach, the stop-cock is turned, so that the fluid may flow back through the outlet. If it does not flow readily, the bag-syringe is attached, and by compressing this a few times a powerful suction force is induced. At the same time compression of the syringe a few times in rapid succession will cause a swashing and churning of the fluid contained in the stomach, so that the walls are thoroughly cleansed. Of course, such an instrument is capable of numerous modifications and improvements, but this gentleman constructed it to meet a special indication, and, as far as I know, independently of any knowledge of the use of the principle involved in medicine."

#### THE ADVANTAGES AND DISADVANTAGES OF HUMAN AND ANIMAL LYMPH.

The proceedings of the Section of Public Medicine at the meeting of the British Medical Association at Brighton terminated with a paper by SURGEON-MAJOR PRINGLE, on the "Advantages and Disadvantages of Human and Animal Lymph." He pointed out that his object in making this comparison was that, judging from the report of the German Vaccination Commission, published in 1885, and very carefully condensed by Dr. E. J. Edwardes, the preference, as given by this very important commission, was undoubtedly in favor of animal lymph. The necessity advanced by the opponents of human lymph for the substitution of animal for human lymph was based on the following four objections: 1. The supposed deficiency in the protective power of human lymph, owing to some unaccountable deterioration in this principle, caused by the passage of the virus through the systems of so many individuals. 2. The danger to health and life, owing to the possible introduction into the system of syphilis or the infection of erysipelas. 3. The difficulty of obtaining sufficient human lymph for any sudden emergency or great demand. 4. The general objection raised to the withdrawal of lymph for other operations. Animal lymph, the speaker said, was supposed to overcome these four objections, as follows: 1. Animal lymph could never become deficient in protective power, owing to its constant reinvigoration from the calf. 2. The dangers to health and life, owing to the possible introduction into the system with human lymph of syphilis and

the infection of erysipelas, could not occur where animal lymph was employed. 3. As long as suitable calves were obtainable, it was maintained that the supply of animal lymph, to meet any emergency or great demand, was inexhaustible. 4. For the same reason, no possible objection could be raised under this point. Dr. Pringle then met the four objections brought forward against human lymph. 1. The objection under the head of deficiency of protective power. In Dr. Pringle's extensive and prolonged vaccine practice in India, details of which he gave, he maintained that, where carefully and systematically practised by arm-to-arm vaccination, this deterioration was unknown, and this was certainly not due to the absence of smallpox contagion or infection. 2. There was a complete absence in the above practice of any risks as regards syphilitic transference, and the infection of erysipelas was unknown. 3. With a properly instructed vaccine staff this limited supply of human lymph was unknown, and where the number of children was small, the knowledge of storing lymph prevented any difficulties under this head. 4. Mutual confidence between the vaccinator and the parents of the children would satisfactorily overcome any difficulty regarding the withdrawal of lymph for future operations. Dr. Pringle argued against the view that animal lymph was more protective than humanized, and quoted an official report in support of the view that a spurious vaccination could exist for years. Further, that blood-poisoning, although not of a syphilitic character, might follow the use of animal as well as humanized lymph, that animal lymph was incapable of storage or despatch with any certainty, and that, unless squeezed out with clamps and forceps, the contents of six vesicles would only supply sufficient material for the inoculation of one person.—*Lancet*, August 21, 1886.

#### TINCTURA FERRI CITRO-CHLORIDI (TINCTURE OF CITRO-CHLORIDE OF IRON—TASTELESS TINC- TURE OF IRON).

R Solution of chloride of iron (U. S. P.), 4 ℥; Citric acid, 2100 grs.; Bicarbonate of sodium, 2270 grs.; Alcohol, 4 ℥; Water, q.s. ad 16 ℥.

Dissolve the citric acid in 4 fluidounces of water, heat the solution to the boiling-point, and gradually add the bicarbonate of sodium. When effervescence has ceased, add the solution of chloride of iron, and cool the mixture. Then add enough water to make it measure 12

fluidounces, and finally add the alcohol. Each fluidrachm contains about  $7\frac{1}{2}$  grains of dry ferric chloride.

NOTE.—This tincture is approximately of the same strength, in metallic iron, as the official *tinctura ferri chloridi*.—*National Druggist*, September 10, 1886.

#### ABSYNTHIN.

According to Merck, the bitter element of the *Artemisia absinthium* L. is easily soluble in alcohol, also in chloroform, less soluble in ether, and almost insoluble in water.

As a remedy against fever it has been tried without much, if any, success. Small doses stimulate, larger doses intoxicate and produce nausea. Roux recommends the absynthin in doses of 0.1 to 0.25 grm. twice daily, fifteen minutes before meals, to create appetite and to prevent constipation, for convalescents and in cases of chlorosis. If there exists a tendency to diarrhoea, he objects to its use. The remedy may be given in gelatin-capsules and in connection with other medicines, such as nitrate of bismuth, etc.

#### EXPERIMENTAL STUDIES OF KEPHIR.

We abstract the following *résumé* regarding kephir from the *Verhandlungen der Med. Gesellschaft zu Würzburg*, 1886, 4, xix. The observations were all made on patients reduced by exhausting diseases, such as diarrhoea, anæmia, and tuberculosis.

1. Kephir increases the urinary secretion appreciably only when used in large quantities.

2. The specific gravity of the urine and the total weight of the solids in the urine sink under the influence of kephir.

3. The nitrogenous tissue-changes are checked.

4. Digestive energy and nutrition in general are invariably raised even in the most exhausted individual.

5. The bodily weight increased materially.

6. The number of the red blood-corpuscles increases.

7. The pains of lung and stomach affections subside in a few days.

8. The sleep becomes more quiet and more refreshing.

9. The body becomes rounder and fuller.

10. The pallor of the face yields to a fresh and red color.

11. Hence we must regard kephir as one of the most effective of all means to recover the

physical powers after a long or exhausting affection.

#### ON APON.

What is apon? A new antipyretic and hypnotic? Neither, but simply the name\* given by DR. POULET to a tincture prepared by himself, according to the *Bull. de Thérapeutique*, as follows:

R Tr. capsici, 200.0;  
Ammon. liquidi, 100.0;  
Essentiæ thymi,  
Hydrati chloralis, aa 10.0;  
Alcoholis (sixty per cent.), 1000.0.

The pepper is digested with the alcohol and the ammonia for a month, then the essence and the hydrate of chloral are added to the expressed liquid, and finally the whole is preserved in a hermetically-closed bottle.

Apon applied locally has been found of great value in hysterical pains, general muscular cold, angina, influenza, muscular rheumatism, dysentery, enteritis, hemorrhoids, seasickness, and suppressed sweats. It is applied on a flannel rag, either pure or mixed, with a fatty oil. Internally, 10 to 20 drops may be given in a little water; shortly after that half a glass of water or tea is drank.

#### IODIDE OF POTASSIUM IN DIPHTHERIA.

DR. STEFF, of Nuremberg, proposed in the *Deutsche Medicinische Wochenschrift*, No. 9, 1886, iodide of potassium as a remedy for diphtheria. He says,—

"Iodine is a direct remedy for diphtheria, because it can be ingested for a long time, and, circulating in the blood, kills the bacteria. We can give iodide of potassium combined with the tincture of iodine; a two to four per cent. solution recommends itself for the first three years of life, and a four to ten per cent. solution for older children, a teaspoonful being given hourly."

Steff claims to have had success with this mode of medication.

#### A REMEDY AGAINST EPILEPSY.

R Extr. fab. Calabar., gr. viiss;  
Spir. æth., fʒiiss;  
Aq. amygd. amar.  
(sive Aq. menthæ pip.), fʒvss. M.

S.—Five to eight drops t. d. for children,  
Eight to fifteen drops t. d. for adults.

### *ON SUPERABUNDANT ALIMENTATION, AND ON FORCED FEEDING; AND ON THE DIET IN GOUT, URIC ACID, AND BILIOUS LITHIASIS.\**

BY DR. DUJARDIN-BEAUMETZ, PARIS, FRANCE.

**G**ENTLEMEN:—In the last lecture I considered the subject of insufficient or spare diet, and showed its application to the treatment of obesity. To-day I shall take up the opposite aspect of the subject, namely,

the effects of superalimentation, and the therapeutic advantages occasionally derivable therefrom.

A diet may be rich in one or all of the alimentary substances described under the head of complete and complex aliments. Sometimes it is the azotized substances which are superabundant, sometimes the amylaceous, sometimes the fatty; drinks may be taken in too great quantity. In this lecture I shall consider chiefly that side of the question which pertains to superabundant azotized alimentation, and its applications to therapeutics, closing with some observations respecting the transformation of azotized matters in the economy.

Superalimentation has been applied to the

\* An abstract of two lectures on Hygienic Therapeutics. From advanced sheets.

treatment of certain pathological states, such as consumptive complaints and leanness from whatever cause. Fattening in man is subjected to the same laws as those which have been established by zootechnics. To fatten animals three conditions are necessary: they must be of a certain breed, they must be stabled or otherwise subjected to confinement, and they must be fed with certain kinds of food. As now there are varieties or breeds of animals which fatten with greater or less difficulty, so also in the human species there are breeds as well as individuals which resist all efforts to fatten them. There are also fat men who eat very little, and there are lean men who are enormous eaters; and in the case of leanness as well as of obesity, heredity plays a great part, leanness and stoutness running in families.

But there is a factor which renders difficult the application of the laws of zootechnics to man; I refer to the fact, which I have mentioned before, that brain-work is a cause of denutrition even greater than muscular labor. Hence if we should condemn a man to absolute physical rest, we might not thereby stop all mental activity, and the organic combustions and denutrition which follow. I cannot, then, accept the general statement of Brillat-Savarin: "Everybody can become fat, provided the proper kind of diet be chosen."

Moreover, the pathogeny of leanness is very complex. Gubler distinguishes three kinds, basing his classification on pathogeny: that which results from insufficient food,—starvation leanness; that which results from excessive waste of the tissues, due to the exaggerated combustions of the economy,—consumption leanness; and that which is of a hereditary nature,—constitutional leanness. You readily understand that the therapeutic results which you are to expect will depend more on the cause than on anything else, hence your first care should be to ascertain the circumstances under which the patient's loss of flesh has arisen.

The treatment of leanness comprehends, then, like that of obesity, a pharmaceutical and a hygienic treatment. I shall say but little about the former. Certain remedial agents have been vaunted; it has been claimed that metals, such as mercury and copper, possess fattening properties. Wyman has pretended that fusel oil (or potato spirit) has such properties in the dose of from 5 to 10 drops. This is by no means proved, and there is but one medicament that can be

clearly shown to cause fattening, and that is arsenic. The popular usage which the inhabitants of Lower Austria, Styria, and Carinthia make of arsenic is certainly in conformity with the physiological effects of the arsenical preparations, which stimulate nutrition in general and increase the appetite. In the treatment of leanness as well as of obesity, hygiene plays the principal part; under this head we are to consider exercise and alimentation.

As for exercise, the less of it the better, is the general rule for those who wish to gain flesh, and it is worthy of remark in this connection that the idle and luxurious life to which the women in Turkey are condemned (I allude especially to those in upper life) accounts sufficiently for the *embonpoint* which characterizes them.\*

It is alimentation, however, which has the chief rôle in adipose tissue development and increase, and when called upon to treat cases of emaciation, your first duty will be to order foods rich in fat and hydrocarbons. In the first rank comes cod-liver oil, which is always to be ordered when it can be borne, then fat meats, cream, and carbo-hydrates are to be used largely as parts of the daily fare. The following table from De Nedats will be useful as giving you the richness in starch of certain alimentary substances from the vegetable kingdom. Below is a second table giving the percentage of fat in the principal fatty foods:

TABLE OF AMYLACEOUS SUBSTANCES.

	Per cent.
Rice.....	74.10
Indian corn.....	65.90
Wheat flour.....	63.00
Unground wheat.....	59.60
Millet.....	57.9
Buckwheat.....	50.00
Wheat bread.....	42.70
Peas.....	37.00
Rye bread.....	36.25
Beans.....	36.00
Cucumbers.....	16.60
Potatoes.....	15.5

TABLE OF FATTY SUBSTANCES.

	Per cent.
Butter.....	91.00
Fresh bacon.....	66.00
Pork.....	50.00
Mutton.....	40.00

\* Meibomius counsels flagellation! as a fattening measure; "it produces," he says, "swelling of the flagellated parts, and causes derivation thither of the nutritive juices!"

	Per cent.
Cooked beef.....	44.79
Raw beef.....	30.00
Yolk of egg.....	30.70
Cream.....	26.00
Neufchâtel cheese.....	41.00
Holland cheese.....	27.50
Parmesan ".....	16.00
Brie ".....	25.70
Eel.....	13.80
Salt herring.....	12.70
Eggs.....	12.50

While in the treatment of obesity soups and stews are forbidden, here they are prescribed. It is well, also, to order much water to be taken with meals. But, I repeat, despite all the care with which you may direct the treatment of leanness, you will often fail, and for reasons which I have mentioned.

In zootechnics, besides the application of the general precepts on the selection of food and the feeding of animals, stuffing is sometimes practised, as is the case with fowls that are to be fitted for market at a given time. For this purpose, besides the ordinary process of cramming down the throat an alimentary paste, certain apparatuses are much in use, such, as the Martin-stuffer, an instrument resembling somewhat the "gavense" of our hospitals.

These methods of gavage we have also applied to man. Two circumstances have seemed to call for gavage: when the individuals refuse to eat, and we have to resort to *forced feeding* in order to save life, or when the stomach rejects food given in the ordinary way, but retains that which is administered by gavage. In cases of the first kind forced feeding is applied to demented persons who are affected with delusions that they are dead, that they have no mouth, stomach, intestine, etc. In order to practise forced alimentation, many devices have been tried to prevent the patient biting with his teeth through the œsophageal tube. The most simple procedure is to pass the sound through the nares. By this tube (which must, of course, be of small calibre) you can easily introduce a thin gruel or a mixture of milk and meat-powder with wine. The meat-powders here render us great service, for their state of cohesion is such that we can readily make of them a nutrient broth which shall be liquid enough to pass through quite small tubes. You will find in the annals of mental alienation a great many cases where life has been prolonged, and even cures effected in melancholic patients, by means of forced alimentation.

Gavage, properly so called, is applied to

cases where the stomach is intolerant and rejects food ingested by the mouth. Since the labors of Debove, and since my own researches, it has been shown again and again that in many circumstances aliments which are introduced directly into the stomach are tolerated, while food swallowed by the patient is rejected by vomiting. In the vomitings of tuberculosis, of pregnancy, in such as are unmistakably of nervous origin, we have been able to feed the patient through the Debove tube. You know that in these cases it is not necessary to pass the tube down into the stomach, for all the purposes of artificial alimentation are accomplished if the end of the tube is made to penetrate only as far as the upper part of the œsophagus. To-day, thanks to cocaine, the passage of the tube is made with great facility.

I once devised a stomach-sound of my own, which I made much use of; but I have had occasion to abandon it for the new Debove stomach siphon made by Galante. I employ only the smaller-sized tubes, and find them both stiff enough and supple enough for the purpose. It is not needful, you understand, to resort to gavage except in cases of vomiting or of total loss of appetite.

When the patient can eat, and with some relish and willingness, you can have recourse to superalimentation without employing gavage. When Debove and I commenced our experimentation on meat-powders we lacked the improvements which have since been made in them. We then used stomach-tubes more than we do now. To-day, save in the special cases which I have mentioned, you can administer the meat-powder directly to your patients. This alimentary preparation, by reason of its high nutritive value in small bulk, is admirably adapted for superalimentation. You may employ mixtures of lentil flour or meat-powder in the form of broth, or you may give the meat-powder alone with chocolate (which constitutes quite an agreeable beverage), or you may incorporate it with milk-punch in the following way: In an empty bowl place a couple of tablespoonfuls of meat-powder; add one or two tablespoonfuls of old rum or Bourbon and half a pint of milk, sweetened *ad libitum*. As for the quantity of meat-powder, you may begin with 100 grammes a day, and gradually increase to 200, 300, and 400 grammes, which may be taken in divided portions during the day.

You all know the remarkable results which have been obtained from superalimentation in the treatment of consumptive diseases.

You will find cases of extraordinary interest recorded in articles by Debove and his pupils, Broca and Wims. I also refer you to published reports of my own and the recent memoir of my interne, Pennel.\* You obtain a marked augmentation of weight, a general amelioration, and in certain rare cases an arrest in the march of the tuberculosis. All these results have been confirmed in Germany at the clinic of Griefswald by Peiper, who has shown us that by administering to phthisical patients meat-powder in quantities gradually increasing from 200 to 500 grammes a day, a striking augmentation of weight has been observed, amounting from five to twenty-two pounds in twelve patients out of every fourteen. In one patient the clinical clerk failed, any longer to find bacilli in the sputum, and physical examination showed a diminution in the local lesions. This man had gained seventeen and one-half pounds in thirty-four days. Superalimentation has, then, proved itself of the greatest utility in phthisis, and must henceforth have an important place in the therapeutics of this disease.

Now that you know the applications of superalimentation to the treatment of consumptive affections, and particularly to that of tuberculosis, I approach one of the most interesting points connected with azotized diet,—namely, the transformation of azotized substances in the economy and their elimination in the state of urea and uric acid. These two bodies play so important a part in the genesis of gout and gravel that I find myself under the necessity of summing up in a few words what we know as to the nature and origin of these effete products of the organism.

Urea is, as you know, represented by the following atomic formula:  $\text{CON}_2\text{H}_4$ . It is extracted directly from urine, or obtained by synthesis; and you are all familiar, in this regard, with the brilliant achievements of my regretted master, Wurtz, who made urea out of cyanate of ammonium. Béchamp has even claimed that, by the direct oxidation of albu-

minoid matters by means of potassium permanganate, urea might be obtained.

Urea constitutes the basis of a series of complex bodies to which has been given the name of the *uric acid series*. It includes compound ureas and ureides; and for more particulars on the subject I cannot do better than refer you to the thesis on Ureides of the regretted Henninger.†

In a general way, it may be said that all the chemists are agreed in considering urea as an amide; it is an amide with carbonic acid, or *carbamide*. I need not here remind you of what is understood in chemistry by an *amide*; you know that it is an ammoniacal salt minus a certain quantity of water. The formula which I place before you shows that in abstracting from neutral carbonate of ammonium two atoms of water you have the formula of urea:

Urea is found in all the tissues of the economy, and a man secretes on an average twenty to thirty grammes a day. We shall see farther on the circumstances which augment or diminish this secretion.

Like urea, uric acid (whose formula is  $\text{C}_5\text{H}_4\text{N}_4\text{O}_6$ ) is found in the normal state in the urine, but in much less considerable quantity, since in the twenty-four hours the normal excretion in an adult man is only 0.58 gramme. Uric acid forms with bases neutral and acid salts; the most abundant of these salts in the economy is the acid urate of sodium, which constitutes brick-dust sediments in the urine, and with whose varying microscopic appearances you are familiar: daggers, halberds, lozenges, etc.

Many views have been put forth as to the origin of urea and uric acid. The first, and which till within a few years has been the prevalent view, is that urea and uric acid are the result of the oxidation of albuminoid substances. When the oxidation is complete there is formation of urea; when it is incomplete it is uric acid which is formed: urea and uric acid being the waste products of organic combustion. This view was founded on both chemical and physiological experiments.

Wöhler and Liebig, in their great work bearing date 1838, had shown that uric acid, in undergoing oxidation, is transformed successively into allantoin, alloxane, and urea.

\* Debove, "Sur le traitement de la phthisie pulmonaire par l'alimentation forcée" (*Bull. de Thérap.*, 30 Novembre, 1881); Dujardin-Beaumetz, "Sur nouveau procédé de gavage" (*Bull. de Thérap.*, 15 Juillet, 1881; *Clinique thérapeutique*, Du Gavage, 4e édition, t. i. p. 404); Broca et Wims, "Recherches sur la suralimentation envisagée surtout dans le traitement de la phthisie pulmonaire" (*Bull. de Thérap.*, 1883, t. cv. p. 289); Pennel, "De l'alimentation chez les phthisiques" (*Bull. de Thérap.*, 1882, t. cii. p. 185); Peiper, "De l'alimentation forcée des phthisiques" (*Deut. Arch. f. Klin. Med.*, 1885, vol. xxxvii.).

† Henninger, "Des Uréides" (*Thèse de Concours*, 1878).

On the other hand, Béchamp, in demonstrating that the direct oxidation of albuminoid matters furnishes urea, had given to this view an experimental proof which seemed indisputable. Experiments made on men and on animals seemed to confirm this position. In examining the quantity of urea and uric acid excreted during the periods of repose and of work, it was shown that there exists between the quantity of urea voided in twenty-four hours and that of uric acid an inverse proportion, and that while during rest the quantity of urea is inconsiderable, that of uric acid is large; conversely, muscular labor causes an increase in the quantity of urea and a decrease in that of uric acid. Ritter's table, which I here place before you, shows this conclusively:

	Quantity of urine.	Total of nitrogen.	Ammonia.	Urea.	Uric acid.
Rest.....	1340 grms.	17.89	0.48	32.90	0.98
A walk of four hours.....	1940 grms.	20.00	0.62	39.25	0.68
A march of four days.....	2120 grms.	20.30	0.59	40.30	0.62

The influence of regimen in the production of urea and uric acid also comes to the support of this view, for the quantity of both of these principles augments with an azotized diet, and diminishes with a vegetable diet and with abstinence.

As for urea the fact is not doubtful, and it is the same with uric acid. Lehmann, in experimenting on himself, found in twenty-four hours the following figures pertaining to the uric acid excretion:

An animal diet.....	1.47 grammes.
A mixed diet.....	1.18 "
A vegetable diet.....	1.02 "

Ranke\* has noted still more marked differences, as the following table shows:

An animal diet.....	0.88 gramme.
A vegetable diet.....	0.65 "

But certainly the most interesting experiment is that which Boussingault has performed on ducks fed on different substances, and the results to which he arrived are as follows:

#### DAILY AMOUNTS OF URIC ACID EXCRETED.

	Grammes.
During entire abstinence from food.....	0.27
After ingestion of balls of clay.....	0.27
" " gum arabic.....	0.29
" " cheese curd.....	10 55

\* Ranke, "Beob. und Versuch über die Aussch. des Harns." München, 1868.

	Grammes.
After ingestion of gelatin.....	10.21
After a new dose of gelatin.....	13.21
Under the influence of a diet of fibrin...	9.10
" " " " flesh...	18.91

Lastly, some direct experiments made by Frerichs and Wöhler had showed that in giving dogs uric acid the sum of urea excreted is increased, and the researches of Stockvis, of Zabelin, of Neubauer, are confirmatory of these experiments.†

The theory which would assign a common origin to urea and uric acid seemed then absolutely demonstrated, and had become generally accepted; it considered uric acid as the incompletely oxidized remnant of an intermediate body, which was destined in the organism of mammals for a higher degree of oxidation. You will now see that another theory has arisen by the side of this one which teaches that urea and uric acid have each a distinct origin.

As for urea, everybody is agreed in considering it as the result of a breaking up of albuminoid matters, whether the latter come from food or from tissue-waste. The experiments of Panum, of Hugounencq, of Darier, those still more recent of Quinquaud,‡ show the intimate relation which exists between urea production on the one hand and an azotized diet on the other. But new conceptions arise of the metabolisms taking place as we push still further the study of urea formation.

Abandoning the theory of Liebig and Wöhler, who taught that oxygen produces the combustion of albuminoid matters and their direct transformation into urea, Shultzen and Nencki§ have maintained that urea results from successive modifications effected in amide acids, glycolic, leucine, and tyrosine.

† Zabelin, *Ann. der Chem. und Pharm.*, Bd. lxx., s. 335; Neubauer, *ibid.*, supplém. iii., s. 326; Wöhler et Frerichs, "Modifications que diverses substances éprouvent en passant dans l'urine" (*Journ. für Prakt. Chem.*, 1848, t. lxxiv. p 60).

‡ Panum, "De la courbe de la sécrétion de l'urée et de l'urine pendant vingt-quatre heures après un repas consistant en une certaine quantité de viande" (*Nordisk Med. Archiv.*, vol. vi. n° 1874); Hugounencq, "Expériences nouvelles sur le dosage de l'azote et la production physiologique de l'urée" (*Thèse de Montpellier*, 1883); Darier, "Recherches cliniques et expérimentales sur les variations de l'urée" (*Rev. med. de la Suisse romande*, t. iii. 65 et 121, Février et Mars, 1883); Quinquaud, "Oscillations et formation de l'urée pendant la digestion des aliments azotés" (*Bull. de la Société de Biologie*, 11 Octobre, 1884).

§ Shultzen et Nencki, "Die Vorstufen des Harstoffs" (*Zeits. f. Biologie*, viii.).

In their estimation, albuminoid substances behave in the following manner in the economy: a portion is destroyed by digestion, another portion, the more considerable, is decomposed in the lacteals and portal circulation into bodies exempt from nitrogen, and into amide acids; the latter are transformed into urea, while the former are burned in the organism and pass out in the form of carbonic acid and water.

Schultzen has undertaken a great many experiments on animals and on man to show the direct transformation of glyocol and of methyl-glyocol, or sarcosine, into urea. These experiments, repeated by Küssner and Salkowski, appear to be demonstrative of the facts advanced by Schultzen and Nencki.

Knierim has put forth another opinion as to the origin of urea; he maintains that urea is not derived from amide acids, but from aspartic acid, and from asparagine.

The same want of agreement is seen when attempts are made to specify the place where this transformation is effected. In the opinion of the majority of physiologists it takes place in all parts of the economy, wherever molecular changes are going on. Nevertheless, the liver has of late years been regarded as the chief centre of urea production, and we see Murchison and Parkes in England, Meissner in Germany, and Brouardel in France, stoutly defend the doctrine of the hepatic localization of urea-genesis, a view which seems to be confirmed by the recent experiments of Von Schroeder,\* who, in applying the method of local circulations to the solution of the problem, has shown the production of urea by the hepatic gland. I set aside as not confirmed another hypothesis which has been made, and which assigns to the kidney the function of urea formation, and I come now to recent views which have been set forth as to the origin of uric acid.

Bencke, Voit in Germany, and Lecorché in France, have maintained that uric acid is not a derivative of urea, but of xanthine.

In fact, if you will cast your eyes over the following formulæ, you will notice that hypoxanthine, or sarkine, xanthine, and uric acid differ only by one equivalent of oxygen, and it is easy to see that the last of these bodies might easily arise from oxidation of the two former:

Hypoxanthine, or sarkine,  $C_5H_4N_2O$ .

Xanthine,  $C_5H_4N_2O_2$ .

Uric acid,  $C_5H_4N_2O_3$ .

As for the part of the economy where the production of uric acid takes place, there are numerous hypotheses which I shall only mention. Ebstein supposes the marrow of bones to be principally concerned in uric acid genesis, Chrzonszczewski refers this function to the connective tissue, Robin to the fibrous tissue, Ranke to the spleen, Bencke to the white globules, Zaleski to the kidneys, and Meissner and Lecorché to the liver.

I am, myself, inclined to hold to the old view of Wöhler and Liebig as to the origin of urea and uric acid in the economy, and believe that this is the only view having a definite bearing on therapeutics and sanctioned by practice. Therefore I regard urea and uric acid as having a common origin, resulting from the oxidation, more or less complete, of the albuminoid matters of the economy, and I will give you the proofs of this when I come to the dietary of gout. If I have dwelt at length on this subject, it is to call your attention to the numerous works which have appeared thereon, and the importance which in biological chemistry is attached to the study of the metamorphosis of azotized matters. I deemed it also of importance that you should be acquainted with what is known of the origin of these two bodies, urea and uric acid, which by their presence in the economy constitute the uric diathesis, which is so common, and which offers a favorable soil for the development of gouty and rheumatic affections. We shall see numerous applications of the details into which I have entered when we come to the next lecture, in which I propose to speak of the hygienic treatment of gout and gravel.

## LECTURE II.

### ON DIET IN GOUT, URINARY AND BILIOUS LITHIASIS.

In the preceding lecture I have treated at some length of superalimentation in its effects on the transformation of azotized aliments in the economy, and on the various theories which have been put forth as to the origin of urea and uric acid. I shall have no more to say on these points, and shall now take up the interesting study of diet in the treatment of gout and gravel, affections which result from the accumulation of urea and uric acid in the organism.

In this lecture, concerned exclusively with hygienic therapeutics, I cannot devote much time to the history of gout, or to the numerous discussions which have arisen between the

\* Von Schroeder, *Arch. f. Experim. Path. und Pharm.*, Bd. xvi., Heft 5 and 6.

solidists and humorists with regard to the pathogeny of gout. But I will endeavor to sum up in a few words the recent hypotheses which have been put forth on this subject.

When Garrod published his treatise on gout there was general unanimity in considering it as giving the clearest explanation of the phenomena observed. According to Garrod, gout results from two pathogenic elements,—uricæmia on the one hand, and impermeability of the kidney on the other.

Uricæmia is due to the abundance of urea in the different humors of the economy, and this excess results either from an alimentation too highly azotized, or from insufficient oxidation of albuminoid matters. As for renal impermeability, when existing, it prevents the removal of the effete products of combustion, and thus favors their accumulation in the economy.

This doctrine has not been accepted by all, and to-day there are two quite opposite theories to explain the pathogeny of gout. According to some, as Bouchard and Bencke, gout is the consequence of a failure in the elaboration of albuminoids, and depends on that state of the economy to which they have given the name of *retarded nutrition*. According to others, however, as Lecorché, it is exaggeration in the functions of nutrition which causes the uric diathesis. Let us briefly examine these opposing theories.

Comparing uric acid with other acids of the economy, Bouchard refers gout to the uric diathesis, and endeavors to show that this acid diathesis depends on too slow a destruction of organic substances. Whence come these acids? They result either from the nature of the food ingested, or from vicious or abnormal fermentations taking place in the digestive tube; vicious fermentations being especially favored by dilatation of the stomach. Hence Bouchard, logical with himself, assigns to dilatation of the stomach a preponderant rôle in the pathogeny of gout.

When once formed, these organic acids are eliminated at different points: the sweat gives issue to formic, valerianic, butyric acids; cholic acid is removed by the intestine, and uric, hippuric, and oxaluric acids by the kidneys. But let some circumstance intervene to modify the play of these different excretories, these acids accumulate in the economy, and gouty manifestations appear. Quite different is the theory of Lecorché.\*

Adopting the new views which give to the cell the preponderant rôle in the dissociation of albuminoid elements, views which I have set forth in the last lecture, Lecorché thinks that gout results from exaggerated dissociation of azotized matters, due to inordinate activity of the organic cells; in a word, hyper-nutrition engenders gout.

Whether gout be the result of exaggeration or of retardation in the functions of the economy, everybody recognizes that the augmentation in the blood of uric acid is the essential cause of gout, and that its passage to the state of biuret determines the gouty paroxysms. The same agreement exists from the point of view of the influence of diet on the prophylaxis of gout, and it is the dietetic treatment of this diathesis which I am going to speak of in this lecture.

In the prophylactic and curative treatment of gout, authorities have maintained the advantage of exclusive regimens, and vegetarians have endeavored to show that by means of entire abstinence from purely azotized aliments gout might be made to disappear; but an exclusively vegetable diet has its disadvantages, as Sydenham was one of the first to point out. Therefore it is the better practice to give to gouty persons a mixed diet, and this shall be the text of what I have to say to-day. I shall take as my basis Bouchardat's important work on the treatment of what he calls the *polyuric diathesis*,—i.e., a diathesis characterized by excess of production or insufficiency of elimination of uric acid, or of the biurates. Let us examine, then, the alimentary hygiene of the gouty under the several heads of foods, drinks, time for meals, and exercise.

As for azotized aliments, all kinds of meat may be used, predominance being given to white meats over those which are too highly azotized, such as venison or wild fowl. Be not too free in the use of eggs, fish, oysters, lobsters; old cheese is to be avoided. Fatty foods are to be eaten sparingly.

Vegetables generally are to be permitted, and should have a large place in the bill of fare of the gouty. Among these may be particularly recommended lettuce, chiccory, artichokes, cucumbers, cardoons, salsify, celery, carrots, parsnips, and potatoes. Radishes, and especially the black radish, may be permitted, as well as the salads (lettuce, dandelion greens, water-cresses), but spinach and sorrel should be forbidden on account of the oxalic acid which they contain. As for cabbage and cauliflower, which contain much ni-

\* Lecorché, "Theoretical and Practical Treatise on Gout." Paris, 1884.

trogen, one should be chary in their usage, as well as the starchy legumes,—beans, peas, and lentils.

As for bread, Bouchardat recommends, as far as possible, to replace this culinary product by potatoes, as is done in England; the importance of this I shall show you more fully when I come to speak of diet in diabetes. As regards fruits, they are all favorable, and the utility of strawberries and grapes has been especially insisted upon. The grape-cure is, in fact, sure to ameliorate the condition of many gouty patients.

As for mushrooms, truffles, and condiments, it is well to exercise great caution in their use.

In reference to drinks much may be said. As a general rule, the gouty person should drink abundantly. Water, which is the best drink, dissolves effete matters out of the tissues and flushes the kidneys, and is the best of diuretics. The alkaline waters are especially to be commended. Wine is not to be absolutely proscribed. What has led to the interdiction of spirituous and fermented liquors is the fact that when taken in excess they are among the most influential factors in the production of gout and gouty paroxysms, and Sydenham truthfully said that "if gluttony engenders gout, the latter is much oftener the effect of wine-drinking."

Wine must, then, be drank very sparingly, and, when taken, should be diluted with alkaline waters. The best wines for gouty people are the old wines that contain but little tannin, such as the light Bordeaux, or the mild pale wines; the sparkling (effervescent) wines, such as champagne, should be absolutely discarded. Scudamore, years ago, pointed out the disastrous effects of champagne on the gouty. The gaseous waters, such as Apollinaris, and the artificial seltzer-waters, should also be interdicted.

The strong beers, such as "stout," Bass's English ale, the Dublin porters, etc., should be proscribed. Garrod has shown us that in England the prolonged usage of these beers produces even in the poorer classes gouty manifestations. There has been much dispute as to the value of cider in gout and gravel. Some authorities (as Dumont) approve of it. Lecorché is, however, inclined to believe that in certain cases cider may be injurious.

In the case of cider, as of beer, the state of purity of the beverage has a good deal to do with the results experienced. As it is the custom at the present day to add alcohol to

the beers of commerce, as well as to cider and perry, one can easily understand the effect of such falsifications in the diet of the gouty. If, therefore, clinicians claim to have seen good therapeutic effects from these fermented beverages, it is because pains were taken to procure an unsophisticated product. It need hardly be said that whiskey, strong wines, "bitters," cognac, etc., are to be absolutely proscribed.

As for tea and coffee, the latter may be taken in moderation, while tea should be forbidden, if for no other reason, because containing oxalic acid, as I shall shortly show you.

The hours for meals should be regulated with care, and the patient should eat slowly and masticate thoroughly. The meal should be plain, and Sydenham's observation on this point is good:

"I believe that the patient should content himself with one sort of food, for if he eats a variety, he is more likely to overload his stomach than if he satisfies his appetite with one kind. You can cure the gout if you can cure the gourmand of his gluttony."

Such are the dietetic rules applicable to gout. They are summed up in the following sentence from Sydenham, whose treatise on Gout (*Podagra*), published in 1683, still contains some of the best things that have ever been said on the subject of treatment: "The patient must observe great moderation in eating and drinking. On the one hand, he must eat no more food than the stomach can digest, and on the other hand, he must not enfeeble himself too much by abstinence; two extremes equally to be avoided, as I have many times proved on patients and on myself."

But the dietetic treatment of gout, if it be the most important, should, nevertheless, be supplemented by other hygienic measures, which I shall briefly indicate. The functions of the intestines, bladder, and skin must be carefully looked after. The podagrous patient must have a free stool every day, and if this cannot be brought about without cathartics, he should take every morning a glass of Pullna or Hunyadi Janos or Bouchardat's laxative, which consists of a drachm to half an ounce of Rochelle salts in a glass of lemonade.

The gouty patient should also regularly empty his bladder every two hours,—Bouchardat insists much on this necessity of complete evacuation of the bladder at frequent intervals,—and according to him, the untimely death of many illustrious men, and of Claude

Bernard in particular, was owing to the fact that they were habitually negligent in the performance of this important duty.

As for the care of the skin, the cutaneous functions should be maintained in a healthy state. This will be promoted by bathing the whole body and by massage every morning. Bouchardat adds once a week to the water of the bath a teaspoonful of essence of lavender, two of compound tincture of benzoin, and half an ounce of carbonate of potassium.

Exercise plays an important part in the hygiene of the gouty, equal, almost, to that of diet, since by exercise the victim of podagra is able to oxidize and burn his albuminoid substances. Exercise under all its forms, and proportioned to the endurance of the patient, should be prescribed; you know the sentence of our immortal fabulist,—

"Goutte bien tracassée  
Est, dit-on, à demi pansée." \*

But he that says gout, says gravel, and this leads me to finish this lecture by some remarks about urinary and hepatic lithiasis.

As for renal lithiasis, it is, as you know, comprehended under two great classes, acid gravel and alkaline gravel; the first includes uric and oxalic calculi, the second, lime deposits and the ammoniaco-magnesium phosphates.

As to the treatment of uric acid lithiasis, I have nothing to add to what I have said with reference to the diet of gout and the general régime applicable thereto.

Oxalic acid gravel, called also "poor man's gravel," because it may be engendered by a diet exclusively vegetable, deserves to arrest our attention a few minutes.

There has been much dispute about oxaluria; some pretending with Bird, Prout, Garrod, Furhbringer, Ralfe, that oxalic acid is found in the normal state in the blood, constituting, when in excess, the oxalic diathesis; others, on the contrary, as Lecorché and Esbach, maintaining that oxalic acid when thus existing in the blood and excretions always comes from food. Without presuming to settle the dispute, I should be disposed from the stand-point of hygienic therapeutics to adopt the latter view, for if it is by no means proved that incomplete oxidation of saccharine and amylaceous substances may cause oxaluria, everybody is agreed in recognizing the preponderant rôle of vege-

table aliments containing oxalic acid in determining this diathesis.

Hence, whenever you meet with cases of oxalic acid gravel, you ought rigorously to proscribe the usage of foods which contain this acid in relatively large quantities; as a guide you will find the following table from Esbach of use:

THE FOLLOWING SUBSTANCES CONTAIN IN EVERY 1000 PARTS OXALIC ACID IN THE ADJOINED PROPORTIONS:

1. *Groceries and Condiments.*

	Grammes.
Black tea, in substance....	3.750
" infused five minutes	2.060
Cocoa.....	3.520 to 4.500
Chocolate.....	0.900
Pepper.....	3.250
Chicory (infusion).....	0.795
Coffee (adulterated).....	0.127
Chervil.....	0.035
Parsley.....	0.006

2. *Farinaceous Substances.*

	Grammes.
White beans.....	0.312
Garden beans.....	0.158
Celery, radishes.....	0.135
Potatoes.....	0.046
Bread of good quality....	0.047
Crust.....	0.130
Crumb.....	0.120
Buckwheat flour.....	0.171
Barley flour.....	0.039
Indian corn flour.....	0.033
Wheat bran.....	0.848

3. *Vegetables and Cooked Herbs.*

	Grammes.
Sorrel.....	2.740 to 3.630
Spinach.....	1.910 to 3.270
Garden rhubarb.....	2.466
Brussels cabbage.....	0.020
White cabbages.....	0.003
Beets.....	0.390
Green beans.....	0.060 to 0.212
Salsify.....	0.070
Tomatoes.....	0.002 to 0.052
Carrots.....	0.027
Celery stalks..	0.025

4. *Salads.*

	Grammes.
Chicory.....	0.103
Endives.....	0.045
Escarols.....	0.017
Corn salad.....	0.016

5. *Fruits.*

	Grammes.
Dried figs.....	0.270
Currants.....	0.130
Plums.....	0.120
Gooseberries.....	0.070
Prunes.....	0.070

\* *I.e.*, Exercise is the best dressing.

	Grammes.
Raspberries.....	0.062
Oranges .....	0.030
Lemons.....	0.030
Cherries .....	0.025
Strawberries.....	0.012

I must call your attention to certain points connected with the above table. It will be seen that tea contains almost as much oxalic acid as sorrel. There is also a notable proportion in coffee, while in this respect cocoa stands almost first. Hence chocolate, tea, and coffee should be forbidden in oxaluria.

You also notice the large proportion of oxalic acid in bran, hence it is that coarse bread favors the development of oxalic gravel.

As for vegetables, the table shows that it is a mistake to forbid the tomato, while allowing spinach. The latter contains per kilogramme 1.910 to 3.270 of oxalic acid, while tomatoes contain only 0.002 to 0.005.

As for ammoniacal deposits, they are always secondary, and the result of fermentation of the urine, brought about by affections of the vesical mucosa. Here, as Guyon has shown, it is the milk diet which gives the best results, and in suppurative pyelitis and suppurative cystitis you should put your patient on a regimen exclusively of milk.

Hepatic calculi have a quite different origin. They are due to the presence of cholesterine in the biliary passages, and demand a special hygienic treatment. These calculi are constituted almost exclusively of cholesterine and bile pigment.

Cholesterine is, as you know, a non-saponifiable fat, which Berthelot's labors have placed among the alcohols. Under certain conditions, which I shall point out, cholesterine is deposited in the bile-passages. Knowing these conditions, you will be able to direct aright the hygienic treatment of biliary lithiasis.

Two circumstances predispose to the precipitation of cholesterine,—either it is in excess in the bile, or, while existing in only the normal proportion, its precipitation is brought about by modifications in the composition of the bile. Excessive production of cholesterine is generally due to one of two causes,—either to a diet too rich in fats, or to overtaxing the nervous system. Flint, as you are aware, considers cholesterine as a product of disassimilation of the nervous system.

With regard to precipitation by modifications in the bile, Thenard (who has well studied this subject) has shown that cholesterine, while remaining at the normal figure

in the bile, may, nevertheless, be deposited when the bile loses its alkalinity, which is most likely to happen under a diet of animal food. Do not forget also that stagnation of bile in the gall-bladder favors this deposition. The dietetic rules applicable to biliary lithiasis easily suggest themselves from the considerations just stated.

You should suppress from the habitual dietary all fatty substances, carbo-hydrates, sugars, and starches which may engender cholesterine. Among starchy legumes, peas ought especially to be discarded, because containing a fatty body similar to cholesterine, as Hœckel and Schlagdenhauffen have shown, and which they have named *vegetable cholesterine*.\*

While on this subject of vegetable cholesterine, I must mention, only to condemn it, a popular notion that carrots constitute an excellent food in hepatic affections, and particularly in biliary lithiasis. This notion seems to be a survival of an idea, based on the old doctrine of similars, called also the doctrine of signatures, whereby a yellow vegetable, like the carrot, was regarded as a specific for jaundice. On the contrary, the composition of the carrot shows it to contain cholesterine, and hence to be unfit for food in biliary lithiasis, as may be seen by referring to Arnaud's analysis.†

Besides the sugar which it contains, the carrot also possesses a hydrocarbon called *carottine*, having for formula  $C_{40}H_{56}$ , and *hydro-carottine*, which is really a vegetal cholesterine. Its main ingredients are, in fact, sugar, carbo-hydrates, and cholesterine, substances which render this vegetable inappropriate for the diet of persons affected with gall-stone.

You will also avoid the too exclusive use of animal food. Lastly, you will urge the moderate usage of eggs, and if you were to sum up the bill of fare of a person predisposed to gall-stones, you would say, never more than one egg a day, a mixed diet of meat and fresh vegetables. All kinds of meat are permissible, but the patient should discard the fatty parts. All kinds of fresh vegetables are proper, and cannot but be

\* Hœckel et Schlagdenhauffen, "Sur la présence de la cholestérine dan quelques corps gras d'origine végétale" (*Acad. des Sc.*, 1886, t. ciii. p. 1317).

† Arnaud, "Recherches sur la composition de la carottine, sa fonction chimique et sa formule; Sur la présence de la cholestérine dans la carotte, recherches sur ce principe immédiat" (*Acad. des Sc.*, 1886, t. cii. p. 1119 et 1319).

beneficial. While starchy foods in general are to be avoided, potatoes may be allowed. Bread should be eaten in great moderation.

Acid fruits are also to be recommended, and Bouchardat\* speaks highly of their utility, but sweet fruits are to be avoided, and pastries should be absolutely forbidden. The meals should be near enough together so that the gall-bladder may be frequently emptied. As for drinks, you may allow wine well diluted with some alkaline water, as Vichy or Vals. Free action of the bowels should be promoted, and the bodily exercise should be sufficient to keep the general functions of the economy in a high state of efficiency. Such are the hygienic rules applicable to biliary lithiasis.

In the next lecture I shall consider a subject of the greatest interest, namely, diet in diabetes.

**A CONTRIBUTION TO OUR KNOWLEDGE  
OF FEVER, AND THE AGENTS WHICH  
PRODUCE OR ARREST IT.**

BY DRs. H. C. WOOD, E. T. REICHERT, AND HOBART  
A. HARE.

(Concluded from page 741.)

THE second drug whose action upon the thermogenic functions of the body we have studied is antipyrin. Clinical experience has certainly demonstrated that the influence of this agent upon temperature in febrile diseases is far greater and more constant than is that of quinine; in correspondence with this, we have found that it is much more apt to decrease the temperature of the normal dog than is quinine. At one time in the course of our experiments we thought that this temperature depressing influence was constant. A larger experience has shown that, though very frequently full doses of antipyrin do depress the temperature of the normal animal, in other cases no such effect is produced. If the antipyrin be given in overdoses it produces violent tetanic convulsions, which are accompanied by a very marked rise of the temperature, amounting sometimes to several degrees. This rise of temperature seems to us to be caused, at least in part, by the convulsions, and may not at all be due to any immediate action of the drug. It is very rapidly developed after the coming on of the convulsion. The convulsions are of cerebral origin, although they had the appearance of being spinal, since, after section of the cord,

they failed to appear in the hind legs, although present in the front legs.

In our investigation of antipyrin our first efforts were directed to determining whether it has any constant influence upon the dissipation or production of animal heat in health. In these experiments the antipyrin was given in doses of one-half grain, or of one grain per pound, to the animal; and in all cases the dogs were in as nearly perfect health as we could obtain.

ANTIPYRIN.

The records of these experiments and the tables in which the results obtained are summarized show that in seven of the experiments there was a decrease in the production and dissipation of animal heat, whilst in two instances both of these functions were distinctly increased. The results obtained are therefore not entirely concordant. The explanation of the two exceptional experiments may, perhaps, be found in the fact that they were made upon very small, feeble dogs, to which was given the largest dose of the antipyrin employed. When administered in very large doses, we have found that antipyrin increases the animal temperature very greatly,—whether by direct or an indirect action is not known. Such increase we have only seen when convulsions have been present, and we are therefore inclined to attribute the rise of temperature directly to the convulsion; but it is possible that the drug may cause increased thermogenesis independently of the convulsive movement. Moreover, it is not at all unlikely that in the exceptional experiments the dogs had a convulsion in the calorimeter, for, unless such convulsion were exceedingly violent and prolonged, it might very well pass unnoticed.

Further, the reasons given during the discussion of quinine—why in calorimetrical experiments with drugs absolutely concordant results are hardly to be expected—are here also applicable.

Whatever may be the correct explanation of the results reached in the exceptional experiments, the whole series show that, in the normal dogs, antipyrin, given in doses of  $\frac{1}{2}$  to 1 grain per pound, usually produces a distinct decrease both of heat production and of heat dissipation. In only one of the seven experiments was the decrease in heat dissipation greater than the decrease in heat production. In one experiment the two functions were equally affected; in five experiments heat production was distinctly increased more than was heat dissipation. These facts prove that, if the change in either function is the

cause of the change in the other function, it must be heat production which is dominant,—i.e., is the function primarily affected and affecting the other function. In other words, we must conclude that heat production in normal dogs is in some way primarily lessened by antipyrin, and that such lessening is followed either as an accompaniment or effect by lessening of the heat dissipation.

The question now naturally presents itself, In what way does antipyrin lessen heat production? But before entering upon the discussion of this question it seems wisest to consider the action of antipyrin upon the temperature of dogs in which fever has been produced by the pepsin-peptone. Our experiments upon the subject have all been made on the plan adopted with quinine.

\* Dog was in calorimeter for both periods (equalled three hours) without interruption. For this reason the figures are duplicated in order to come properly into the table.

† Same as above, only the periods equalled two hours instead of three hours.

An examination of the table of heat dissipation will show that in Experiment 66 there was a much greater dissipation of heat the first hour after the pepsin and antipyrin than in the first hour immediately after the pepsin alone, but if the whole time of Experiment 66 be considered, the increase in the heat dissipation after the pepsin and antipyrin was very distinctly less than after the pepsin alone. This experiment is, therefore, in exact accord with the results reached in 67 and 68, for, it must be remembered, in Experiments 67 and 68 the whole time after the injection of the drugs was studied at one calorimetrical run.

Considering next the table of heat production, we find that the readings are parallel with those of the table of heat dissipation. Taking each of the three experiments as a whole, there is a very decidedly lessened increase of heat production after the injection of the antipyrin and pepsin as compared with the increase after the pepsin alone. On the other hand, there was an augmented increase of heat production for the first hour after the injection of the pepsin and antipyrin in Experiment 66 as compared with the first hour after the pepsin alone on the previous day.

This is exactly as in the heat dissipation. The conclusion must be drawn that antipyrin diminishes in pepsin-peptone fever both heat dissipation and heat production.

When we come to study the question as to whether the heat dissipation or heat production was most profoundly diminished, we find that in Experiment 66 during the three hours in which the animal was in the calorimeter the first day after the pepsin, in round numbers 42 more units of heat were dissipated than ought to have been if the animal had re-

mained without fever. Thus  $(27 \times 2) - 12 = 42$ , whilst, on the second day after the pepsin and antipyrin, there was no increase in heat dissipation,  $24 (12 \times 2) - 0$ . In regard to heat production in the same experiment, there was, on the first day after the pepsin alone an absolute increase of 69 units  $(29 \times 2) + 11 = 69$ ; but on the second day there was an absolute lessening of 12 units in the heat production,  $18 - 30 = 12$ . Experiment 66 may very well be expressed in the following table:

	First day.	Second day.	Difference.
Heat dissipation.....	42	0	42
Heat production .....	69	— 12	81

It is perfectly plain that heat production was affected in Experiment 67 much more than was heat dissipation.

In Experiment 67 heat dissipation on the first day after the pepsin alone was for the three hours during which the dog was in the calorimeter increased 90 units. For the corresponding period in the second day after the pepsin and antipyrin the increase was 54 units. Heat production was increased the first day 99 units, the second day 60 units.

	First day.	Second day.	Difference.
Heat dissipation.....	90	54	36
Heat production.....	99	60	39

In Experiment 67, therefore, antipyrin affected heat production more than it did heat dissipation.

Computing Experiment 68, and stating the results in tabular form, as in the other similar experiments, we find,—

	First day.	Second day.	Difference.
Heat dissipation.....	66	48	18
Heat production.....	76	68	8

In Experiment 68 heat dissipation was more profoundly affected than was heat production.

So far as relates to the relative action of antipyrin in the two functions of heat dissipation and heat production, our experiments do not yield accordant results. Twice heat production was more affected than was heat dissipation; once dissipation was the more influenced. The most probable conclusion that can be drawn from all our experiments is that antipyrin affects more pronouncedly, both in health and in the fevered dogs, heat production than heat dissipation, but sometimes dissipation seems to be the more influenced. It is possible that if Experiment 68 had been

run during the whole period of the fever instead of the two hours the results would have been in accord with those of 66 and 67, for it was precisely in the latter stages of the fever that the action of the antipyrin seems most pronounced.

The next question which presented itself for solution was, Is this action of antipyrin upon the animal temperature due to an influence exerted upon the circulation, or is its effect produced in any other way? In order to determine this we have made a series of experiments upon the effect of antipyrin on the temperature of the dog suffering from fever. The records of these experiments are as follows:

#### EXPERIMENT 69.

Tracing showing effect of the injection of 10 grains of antipyrin at 3.05 P.M. Injection begun at A and ended at B.

*Experiment 69.*—Antipyrin alone; weight of dog, 24 pounds. No pepsin given. Effects of antipyrin on normal temperature and blood-pressure.

5.41	.....	.....	.....	.....	Killed dog.

Dog struggling violently ever since injections. Never quiet more than a minute. Howling.

Of these experiments, the first (Experiment 69) shows that in the normal dog the fall of bodily temperature produced by antipyrin is not the result of any general action upon the circulation, since the arterial pressure stood at from 170 to 190 at a time when the rectal temperature was 104.5° F., and from 170 to 180 after the rectal temperature had fallen 3° F.

The second experiment (Experiment 70) is interesting as showing that, when the violent convulsions produced by antipyrin are fully developed, the rectal temperature rises very decidedly, which rise is probably produced by the convulsion and not by any direct action of the antipyrin.

The third experiment (Experiment 71) proves that the fever produced by pepsin filtrate is controlled by antipyrin without the circulation being notably affected. Under the influence of the pepsin the rectal temperature was put up from 102.2° to 107.7°, the arterial pressure falling from 196 to 170, and then, after the administration of antipyrin, the temperature fell in three-quarters of an hour 5.4° F., with only a very slight further reduction of the arterial pressure. The mere withdrawal of the heat would, we think, be enough to produce this fall of arterial pressure.

In an earlier portion of the present memoir we demonstrated that there is no necessary connection between the arterial pressure and the bodily temperature. In accord with this, the experiments that we have made upon the bodily temperature and blood-pressure under the influence of antipyrin prove that antipyrin diminishes the bodily temperature without affecting the arterial pressure. Our previous experiments have shown that the fall of the bodily temperature produced by antipyrin is the result of a lessened production of animal heat. It follows from all this that antipyrin

lessens the production of animal heat without affecting the arterial pressure. As it is hardly possible that there could be any effect upon the circulation sufficiently powerful to markedly influence thermogenesis without such effect being registered in the general blood-pressure, we are forced to conclude that antipyrin in some direct way influences the chemical alterations of the body.

Up to this point we believe that the matter has been one of experimental determination, but beyond it we are at present forced to theorize simply. Antipyrin may stimulate the inhibitory heat-centre of Setschenow, and thereby check the chemical movements of the organism, or it may have some direct relationship with the various protoplasmic masses of the system, and by an immediate action upon them lessen their chemical activities. The first of these theories or suppositions seems to us most probable, although we cannot at present offer proof of its correctness. In accordance with it the rise of bodily temperature (and apparently of heat production) which we have seen follow the exhibition of overwhelming doses of antipyrin is readily explained as the result of a paralysis of Setschenow's centre. As is universally acknowledged, many nervous stimulants become in overdoses paralyzants; and in accordance with the theory which we at present favor, antipyrin in moderate dose acts as a stimulant to the inhibitory heat-centre, lessens the production of animal heat, and tends to decrease the bodily temperature; but it is possible that when in large quantity it paralyzes the inhibitory heat-centre, and thereby removes the natural check of the chemical movements of the body, which removal is necessarily followed by a great increase in the chemical movements and in heat production.

#### *CORROSIVE SUBLIMATE IN THE TREATMENT OF CHRONIC BRIGHT'S DISEASES.\**

BY JOHN C. PETERS, M.D., NEW YORK.

THIS is comparatively an old remedy, for it was largely used in the New York Hospital as far back as 1842 or 1843. But it is one which experience has shown is exceedingly liable to fall into unmerited neglect, for

\* Read before the Section on Materia Medica and Therapeutics of the New York Academy of Medicine, October 20, 1886.

chronic Bright's disease is a disorder which sooner or later must terminate fatally in the majority of instances. Hence all remedies against it are apt to come in disrepute, simply because, however useful and however successful they may frequently be, they will always be summarily thrown aside by some experimenters merely because they do not cure or relieve all cases, under all, even the most unfavorable, circumstances.

I had the good fortune not only to watch the first case, which recovered almost marvellously under this treatment, but many other cases under the care of Drs. John A. Swett, Joseph M. Smith, John H. Griscom, Wotherspoon, Augustus Elliott, W. W. Jones, Israel Moses, Gustavus A. Sabine, and others who were successively attending or house physicians or pathologists of the New York Hospital over forty years ago.

I think, and am in fact very sure, that I first suggested the remedy to my friend and classmate Dr. Wotherspoon, then house physician to the New York Hospital, and he brought its claims before Drs. Swett and Smith, who were the attending or consulting physicians.

The first publication about it was made by Dr. Swett in the *New York Journal of Medicine* for July, 1844. He there gives two cases, first that of Elisha Lynch, who was excessively dropsical, while his urine was not only loaded with albumen, but so scanty that coma was impending. I well recollect the remark of Dr. John A. Swett, "This is a case we will know more about in a few days," meaning that we would see it in the dead-house. Digitalis, apocynum, gamboge, cream of tartar, and elaterium all had failed.

The corrosive sublimate was given,  $\frac{3}{8}$  of a grain in 3i doses of tincture of cinchona, every four hours at first, and then, as time pressed, every two hours. It acted decidedly as a diuretic, soon increasing the urine to four pints a day. It removed all the dropsy, except slight œdema of the feet, but much albumen still remained in the urine. Sleep, appetite, and strength returned. It acted as a depurative tonic, and the patient looked well, having greatly improved in flesh and color. Commencing œdema of the lungs had also been removed. Either corrosive sublimate or the cinchona had acted as a blood tonic. The second case was very similar. After the failure of many other remedies, corrosive sublimate was given in  $\frac{3}{8}$ -grain doses three times a day for seven weeks, when the patient was greatly improved

in every way. His dropsy was gone, but the albumen remained.

I cannot help pausing here to mark the fact that the remedy was thought worthy of the attention of so great a pathologist, diagnostician, and clinical teacher as was then the late Dr. John A. Swett.

And also to the fact that the corrosive sublimate, with the aid perhaps of the Peruvian bark, acted as a restorative and blood tonic, and depurative.

Whether the mercury merely removed the urea and other blood-poisons, which obtain in uræmia and in some Bright's diseases by means of increased excretion through the kidneys, or whether it absolutely antagonized or neutralized, or in some other way counteracted them, as mercury and iodide of potassium does the syphilitic poison, we know not.

That extremely cautious and painstaking practitioner, the late Dr. Joseph M. Smith, took up the new remedy in 1842, I believe, and possibly before Dr. Swett, but he did not publish anything until 1862. In the mean time, Dr. John H. Griscom, who, like Drs. Swett and Smith, was a consulting physician of the New York Hospital, published two successful cases in 1844 in the *New York Medical Journal*. In one case he commenced with  $\frac{1}{16}$  of a grain, but increased the doses to  $\frac{1}{4}$ -grain three times a day; they were also given in the tincture of cinchona. Recovery took place, and the albumen disappeared entirely. The other case was notably improved, but was not completely cured. The patient seemed well, but the albuminuria persisted. The same tonic and restorative effects of the remedy before alluded to were noticed.

In 1846 I gathered the experience of the New York Hospital from the house physicians,—Drs. Wotherspoon, Augustus Elliott, W. W. Jones, and Israel Moses,—and from my own notes. All these physicians and Dr. Gustavus A. Sabine, who was the pathologist of the hospital, took great interest in the new treatment, which seemed more successful than any which had been adopted previously. Up to this time about twenty-five cases had been treated, of which five or six had died. Some of the cases which recovered had been very severe, the dropsy was extensive, the urine often almost suppressed, while coma and œdema of the lungs were partially developed. Such cases had usually died promptly under the ordinary treatment, but almost all quickly improved under corrosive sublimate, and often left the hospital apparently quite well. But the albumen and casts disappeared from the urine

in a few cases only, while in some they were diminished very decidedly; in others they even seemed to be increased.

Hence the remedy effected an absolute cure in a few cases only; but it certainly often saved life for the time being. Its most marked obvious effect was an increase in the quantity of urine, which often rose from half a pint to three quarts and more per day, followed by a steady diminution of the dropsy, and gratifying relief from all the most urgent symptoms.

This diuretic effect of corrosive sublimate was then regarded as almost peculiar to Bright's disease, for in a great many patients who took the remedy for other disorders it did not increase the urine in a single case, as far as was noticed or recollected.

About this time strong prejudices were aroused against the use of corrosive sublimate. Dr. Swett, one of its greatest advocates, had died, Dr. Griscom was no longer a hospital physician, and if it had not been for the steady advocacy and even enthusiastic endorsement of it by Dr. Joseph M. Smith, the remedy would have fallen into oblivion.

Dr. Smith did not publish his experience until 1862, in the Bulletin of this Academy for that year. He, as is well known, was also consulting physician to the New York Hospital. He says this energetic preparation has now been used with great success for twenty years in the New York Hospital. He also says it generally induces copious diuresis, and in this way rapidly diminishes the dropsical swellings.

Dr. Bartholow recommends it in chronic interstitial nephritis, when the kidney is small, hard, contracted, rough, granular; in short, sclerosed: viz., when there is hyperplasia of the connective tissue, and that is the principal disease of the kidney. He says he has observed cases in which corrosive sublimate, administered in the small quantities of  $\frac{1}{10}$  of a grain, for a lengthened period, effected cures under apparently very unpromising circumstances.

Dr. Loomis is more guarded in his recommendation. He says, "At one time mercurials were extensively employed in chronic parenchymatous nephritis by keeping up its constitutional effects for months. This plan is now partly abandoned, but there are some, however, who claim that the bichloride may be employed. I shall, in considering the cirrhotic kidney, refer to a class of cases in which the administration of this form of mercury is admissible."

He also says, "It has been claimed that the

long-continued administration of mercury in small doses has the power to arrest or prevent connective-tissue development; but there is no evidence that it has such power. Besides, in most instances, the cirrhotic kidney is developed in connection with a gouty or rheumatic diathesis, which most positively contraindicates the prolonged use of mercurials. Mercurials can be employed with possible advantage only in those cases in which cirrhotic kidney is developed in connection with a cirrhotic liver. The bichloride is the preparation usually employed in such conditions." We will see anon that Dr. Loomis also recommends it in waxy degeneration.

Dr. Broadbent says, "In the numerous cases of albuminuria in the London Fever Hospital, towards the decline of the affection, when only small quantities of albumen remain, mercury in limited doses usually leads to the entire disappearance of the albumen."

Fothergill says, "Mercury is a remedy which should be resorted to cautiously. While a quite safe measure in the hands of so careful a physician as Dr. Broadbent, it may be a very dangerous agent in the hands of some."

Dickinson, p. 87, says he gives a mercurial purge as often as he sees a case of acute renal dropsy in an early stage, and presumably also in acute exacerbations of chronic cases.

Harley, p. 312, says, "In the amyloid variety of renal degeneration the judicious employment of the bichloride of mercury is often of much use, but salivation should not be allowed to take place. This rarely happens with corrosive sublimate, as it is so soluble that it passes readily out of the system by way of the kidneys. Port wine and nutritious food," he says, "are useful, almost necessary, adjuvants."

Dr. Loomis (see "Diseases of the Lungs, Heart, and Kidneys") says, p. 516, "If amyloid degeneration depend upon syphilis, you will at once make use of antisyphilitic remedies. Iodide of potassium and mercury are the most prominent remedial agents. Both of these remedies have gained some favor in the treatment of Bright's disease, and there are those who employ indiscriminately one or the other, or both of them. The benefit derived in certain cases from their use is undoubtedly due to their power over syphilitic manifestations. In such cases the long-continued use of small doses of mercurials will generally be followed by marked improvement."

As all the preparations of mercury have lately been decreed to act in the same way, viz., as corrosive sublimate, by means of the muriatic acid in the gastric juice, I may be allowed to quote here the use of calomel in heart and kidney dropsy, as given by recent Hungarian and Austrian physicians, who found that 3-grain doses, three or four times a day, were generally followed by abundant diuresis. Sometimes this diuretic action of calomel appeared on the second day, with such intensity that the patients were scarcely able to retain their urine. This polyuria may last from five to fourteen days.

Digitalis, convallaria, adonis, and caffeine are sometimes found unsatisfactory. The use of digitalis often has to be intermitted. Here it is where calomel comes in play. It has increased the urine within a week from thirty ounces a day to one hundred ounces, and in one case from ten ounces to one hundred ounces.

The conclusions are,—

1. Calomel is a prompt diuretic and hydragogue in cardiac dropsy, its action being more speedy than is that of digitalis.

2. It removes not only oedema of the tissues, but also effusions in the great cavities.

3. Diuresis generally comes on suddenly on the third or fourth day, when it is advisable to discontinue the remedy, and only to resume it when the urine again becomes scanty.

4. Oedema consequent upon nephritis, or obstruction to the portal system, and inflammatory exudations, do not appear to be influenced favorably by the mercurial; and even in cardiac dropsy, when the urine is very albuminous, the action of calomel seems to be retarded, no effect being observed in many cases until the fifth or sixth day. It is, perhaps, in these cases that corrosive sublimate, as a more soluble and active preparation, may act more promptly.

Thus we have seen that corrosive sublimate has been found by some very reputable physicians useful in several of the varieties of chronic Bright's disease.

In chronic catarrhal, or tubal, or parenchymatous nephritis milder remedies, like citrate or acetate of potassium, liquor potassæ, etc., may be tried first, aided by buchu, which Fothergill lauds so much. But sooner or later recourse may be had to corrosive sublimate, for which the fluid extract of buchu will prove a good and acceptable vehicle. We have also seen that it is useful in some cases of cirrhotic or even lardaceous kidney, and there seems no special reason why it

should not also be restorative in that most common and most important variety of kidney-disease, viz. : chronic diffuse nephritis.

This is multiform and harlequin-like in its appearances. The most common form is that which is often called the "atrophied kidney," which is wrongly decreed always to arise from pure interstitial nephritis.

Another variety is "the large white kidney," which is generally attributed to pure parenchymatous nephritis.

Another and peculiar variety of chronic diffuse nephritis is produced by arterio-capillary fibrosis and by cardiac lesions in the place of the ordinary chronic congestions.

Another common form is that in which the kidney is hardly changed at all in its size, color, or gross appearance. Except for the adherence of its capsule it resembles a normal kidney.

This apparent perplexity, multiform appearances, and confusion are easily explained.

In all these different varieties of chronic diffuse nephritis there are morbid changes in the tubes, the Malpighian bodies, the stroma, and the arteries; but sometimes the disease, or rather chronic inflammation, prevails more in one direction or part than in others. In fact, there is often a great variance in the degree of development of the lesions and the gross appearances of the kidneys.

In some cases the chronic inflammation affects more the epithelium of the tubes and the endothelium of the Malpighian bodies, and then resembles *chronic parenchymatous nephritis*, in which the morbid changes are strictly confined to these parts. Pure and simple chronic parenchymatous nephritis, according to Delafield and Prudden, is really not a very common disease. It is marked by the presence of the large white kidney, and its clinical history, of course, very closely resembles that of chronic diffuse nephritis, which has developed most in the direction of the tubes, parenchyma, and Malpighian bodies.

Again, true, pure, and simple *interstitial nephritis*, marked by great development of the stroma or connective tissue, like that in cirrhosis of the liver, does exist, but not nearly so frequently as it does in connection with chronic diffuse nephritis, which has progressed most in this direction. The atrophied kidney is supposed by some to be the invariable attendant on chronic interstitial nephritis, but the larger number of small, hard kidneys belong to the class of chronic diffuse nephritis.

To recapitulate. There are three great varieties of chronic nephritis :

1. Parenchymatous, generally with the large white kidney.

2. The interstitial, with the small, hard granular kidney.

3. The diffuse or general nephritis, which is the most common and important of all, which may attack the parenchyma and tubes predominantly, and then closely resemble pure parenchymatous nephritis, or it may attack the arteries and connective tissue more particularly, and then mimic interstitial nephritis, with the small, hard, granular kidney.

Corrosive sublimate is possibly a specific against the curable or not too far advanced cases of chronic diffuse nephritis, and there is no reason why it should not be equally useful against chronic parenchymatous and chronic interstitial nephritis.

But there will always be a large number of cases of all three of these varieties of kidney-disease in which no absolute and perfect cure is possible, but only palliation and prolongation of life. Hence too much must not be expected, and a hasty rejection or abandonment of a good remedy should not be indulged in. Richardson says in some cases life may be prolonged almost indefinitely, and the bodily and mental powers retained with so little loss that the patient may be equal to most of the duties and some of the pleasures of life. For the kidney is not equally affected throughout all its parts, and the less injured portions may carry on reasonably well the depurative functions. We must conserve what is left of the kidneys.

Theoretically, corrosive sublimate should be a good remedy against the small, hard kidney, and also against the arterio-capillary fibrosis which so often attends it.

Bence Jones says the salts of mercury act chemically on the organic matters with which they come in contact. The more soluble the preparation the more certain is the action on the different organic substances with which it comes in contact. The solubility of corrosive sublimate in a solution of albumen, like that contained in the serum of the blood, is the cause why this substance is capable of passing quickly into every texture of the body, and when there the same increased chemical and vital action takes place; as we see occurs in the gums and salivary glands as among the earliest signs of the constitutional effect of mercury.

The salivary glands are very different

organs from the kidneys, but mercury may act upon the latter somewhat as it does upon the former. Under mercurial action the gums become spongy, the tongue soft and swollen, the salivary glands also softened and enlarged, while they and the mucous membrane of the mouth and throat may secrete mucus and saliva by the pound. All this is very different from, if not the exact opposite of, sclerosis.

It is also possible that it may cause an increased secretion of urine from the kidneys in the same way that it causes pounds of saliva to flow from the parotid, submaxillary, and sublingual glands.

Mercury is one of the few remedies that will reduce and remove the induration of hard chancres, and no disease causes a deeper cachexia than syphilis, which mercury will remove.

Mercury increases all the secretions, including those of the urinary organs. If there happens to be anywhere a recent interstitial deposit of fibrin, or a collection of serum, its absorption is promoted, newly-formed callus is dissolved, and the cicatrices of newly-closed wounds open afresh.

To get the full effect of corrosive sublimate upon the kidneys, salivation must be sedulously guarded against.

The use of mercury in scrofulous and cachectic subjects has always been viewed with some fear. But the orthopædic surgeons of this city use corrosive sublimate fearlessly and very successfully in scrofulous affections of the joints in small or what they call tonic doses, and with such great success that some of them have inferred that more than an usual proportion of these cases are really syphilis in a masked form, so closely resembling scrofula in all its manifestations that a positive diagnosis cannot be made between them.

We may allude here to the large number of cases of chronic arteritis, which are really syphilitic in nature.

Senator, who is almost entirely sceptical about the efficacy of medicines in Bright's disease, approaches this view in a slight degree when he says there is at most (or at least) one drug, viz., iodide of potassium, which must be allowed to possess a certain amount of efficacy in some forms of chronic nephritis. He says he refers to the albuminuria and not to the other symptoms, such as the dropsy and asthmatic attacks, for which we possess really efficacious remedies. Again, in some diseases mercury is known to increase the proportion of red globules in the blood.

Drs. Wm. H. Thomson, Francis Delafield, N. M. Schaeffer, Drs. Boldt, Bunall, and others all spoke favorably of the restorative and tonic effects of small doses of corrosive sublimate in some of the forms of chronic Bright's disease and in some cachectic disorders.

### *AGAINST THE GERM THEORY OF DISEASE.*

BY MORRIS LONGSTRETH, M.D., PHILADELPHIA.

NO subject in medicine during the last ten years has occupied so much thought and given rise to so much research and experiment as the Germ Theory of Disease. Scientists everywhere are busy gaining knowledge concerning the infinitely small organisms suspected of being the cause of maladies; and latterly this subject has become prominent in every household. While the student is searching in his laboratory, with the aid of the microscope, for his microbes, the housewife is ordering the water to be boiled and distributing disinfectants, eating and breathing in fear of the attacks of these little organisms, which she hears that powerful lenses have discovered to be everywhere present. No one has brought this subject so intimately to general knowledge as the French chemist Pasteur, and no one could have been more patient in the minuteness of his experiments.

There have been many theories in past times about the mode of communication of disease which we have not now the opportunity of discussing, and we will simply say that the germ theory of to-day is this: That disease is caused by the action of microbes on our organisms, and that these microbes are infinitely small vegetable growths. Years ago the idea was that disease spread from person to person by a virus, a poison indefinite in character, which had its origin in our bodies, and which could be elaborated either within or without the body, and was spread by immediate contact or through the air. This virus was regarded as a part of our tissues, or was something created as the result of morbid action. Pasteur is trying to teach us that diseased tissues are themselves innocuous and incapable of communicating disease, but that the microbe or bacillus alone is the worker of evil. This is the same doctrine which he promulgated in relation to the fermentations and putrefactions. Liebig held to the old theory in relation to these processes, that it was a transformation or a change of form in

the matter which produced fermentation and putrefaction. The introduction of minute organisms has led us to pass from the old theory to a new one for both fermentation and disease. Thus intimately are these two questions connected, and a review of Pasteur's work shows that he passed directly from his experiments in the breweries to his observations and investigations in the hospital wards and the laboratory. In his mind the theory of germ diseases rests on the same basis as the theory of fermentation, and his proofs of the one are of the same nature as those of the other. Consequently it now behooves us to examine his proofs for his exclusive theory of fermentation, in order that we may be in a position to judge of the validity of his experiments in the artificial production of disease.

Pasteur was enabled to formulate his theory of putrefaction and fermentation through his previous studies of the question of spontaneous generation. His attitude towards this latter subject, prior to the commencement of the investigation, was an unfortunate one for arriving at an unbiased conclusion, since, as he himself says, he undertook the work for the purpose of disproving the possibility of the spontaneous generation of the low forms of life which are found constantly present in putrefying and fermenting matters. Is such a mental condition a fair one towards a subject? Is it not always easy to offer an unlimited number of experiments, so arranged as to support and apparently demonstrate a previously formed opinion? His experiments were based on the same principles as those proposed in the early studies of this question, which in the hands of some investigators had led to one conclusion and in the hands of others to an opposite one. The method pursued in these investigations is essentially the following: Take a solution of organic matters, or of some of their components, boil it for a long time, place it in a perfectly clean flask, exclude the air by sealing, and expose the flask containing the solution to a moderate temperature. Pasteur claims that if all proper precautions are taken no evidence of life will be found within the flasks, even after an indefinite period of time; in other words, that putrefaction and fermentation are consequently prevented, and that spontaneous generation is impossible.

Pasteur is much to be admired for the minute care with which he has performed these experiments, and the unsurpassed skill with which he has arrayed the testimony to logically prove his belief. But do his experi-

ments in spontaneous generation conclusively demonstrate the point at issue in respect to fermentations and putrefactions and the vital question involved in the germ production of disease? His theory of fermentation is an exclusive one. He teaches that lower organisms alone are able to produce a fermentation, and, consequently, microbes only are able to set in motion the train of events which we see in the symptoms and morbid changes in our bodies in disease.

The experiments in spontaneous generation are not conducted in the same manner or under the same circumstances as in nature we see putrefaction and disease occurring. Let us consider what are the important differences distinguishing them. First take Pasteur's culture-fluids. These, he insists, must always be dilute, transparent solutions, from which all traces of organized tissue have been removed. These solutions, he says, are sufficient for the growth and nourishment of these low organisms; why cannot these organisms also spring spontaneously from them, if it is possible, under any circumstances, for them to originate *de novo*? It has never been contended by the defenders of spontaneous generation of low organisms that they could arise from nothing, and it would be well for Pasteur and his followers to comprehend fully the difference between nothing and something. Some of the earlier experimenters, not recognizing this difference, employed the gaseous elements of which the lower organisms are composed—oxygen, hydrogen, nitrogen, and a little charcoal—in their culture-flasks, and waited to see if new organisms devoid of parents would spring into existence. Pasteur is a trifle more generous in his ingredients, in that he uses organic solutions possessing a greater expectation of life because once alive. Trials with such weak dilutions do not tell us much in relation to the putrefaction or the productions of diseased conditions of our bodies. Meat or our own tissues should be used. With such matters, instead of dilute infusions, we should be close to the question whether our tissues can produce a poison or virus capable of causing disease, and whether they can putrefy unassisted by lower organisms. With such materials for experiments, we should be better able to decide whether tissues, dying but not chemically dead, are capable of transforming themselves into those lower organisms which swarm in them after their vital energies have ceased. This was the power which the earlier investigators contended did reside in all or-

ganized tissues. Needham, the earliest experimenter, called it the vegetative or productive force, and it behooves us to learn whether this force does exist, rather than waste time in trying experiments to see if something can arise from nothing.

In these investigations all recognize the necessity for cleanliness of the experiment flasks. A dirty tube vitiates any experiment, either in chemical researches or in those on spontaneous generation. There is no need for Pasteur to insist on such minutiae so strenuously, meanwhile disregarding the main point.

Needham's boiling mutton fat possesses a degree of heat quite as efficient for the destruction of the spores of pre-existing organisms in the culture-tubes as the heat of Pasteur's sterilizing ovens; and yet Needham's mutton gravy swarmed with countless organisms. His experiments resemble Pasteur's, save in the fact that the former used a rich organic material and the latter uses a solution of a little sugar candy, tartrate of ammonia, and ashes of yeast, in all not stronger than 10 parts in 100 of water. The heat of the boiling fat far exceeds Pasteur's sterilizing temperature. The difference in the results cannot be supposed to reside solely in the virtue of the sterilizing oven.

It is the fashion, however, nowadays, if an experiment flask shows any sign of life, to say, if there is no discoverable leak in sealing it, that it has not been long enough in the sterilizing oven. The appearance of life in a flask is at once denounced as a "failure." Failures may be due, of course, either to insufficient sterilization, or to a leak. But how is a "success" (the production of life) ever possible if it is always to be condemned immediately as a failure? These men are so convinced of their theory that if a fiat of the Almighty was sent forth calling into existence a new being, it would be unanimously condemned as a "failure," or as "not sufficiently sterilized."

Another point, much insisted on but really of little moment in these experiments, relates to the admission of air to the culture-flasks. In the older investigations, the air was driven out and excluded in hermetically sealing the flasks, and it was claimed the vacuum or the lack of oxygen prevented the growth of the lower organisms, and delayed or prevented fermentation and putrefaction. Various devices were employed to admit pure air, but it has been found that all necessary conditions are fulfilled by placing in the mouth of the

flasks or culture-tubes a large plug of cotton-wool. This cotton admits air, and at the same time keeps out the atmospheric impurities.

A number of fallacies are to be found in the arguments on spontaneous generation, based on the results of admitting pure or contaminated air. It will suffice to point out one only. Claude Bernard devised the following experiment in refutation of Pouchet's observations. The experiment is one familiar to the older workers, and has been imitated by many since, especially by Pasteur and John Tyndall. The object of the experiment is to show that the boiled contents of a flask remain unchanged if the spores of lower organism floating in the air are prevented from entering, or in other words, that if a culture-flask shows signs of life there must have been a leak. Bernard took two flasks containing sterilized fluid, and, after boiling them, hermetically sealed them, and found they showed no signs of life. Then into one flask the circumambient air was admitted by breaking the seal, the flask being subsequently resealed. Into the other flask superheated air only was allowed to enter after passing through a tube filled with red-hot pieces of porcelain, and then this flask was resealed. The result was that in the first flask, with natural air, life made its appearance; the contents of the second flask remained unchanged. The argument from this result is that, as the air is full of the germs or spores of lower organisms, the spores entered one flask freely, while to the other their entrance was prevented, or they were destroyed before entering, by the red-hot porcelain. This argument would be conclusive if Bernard and others had shown, in the first place, that the air contained spores of lower organisms, and nothing else but the spores; secondly, that the spores did actually enter the flask. But we know that the circumambient air contains a great many things; it may contain spores,—they are very difficult to show, however,—and it certainly does contain portions of the tissue of our bodies,—abundance of this material can be found around a man busy at experimental work; it contains quantities of organic matters and inorganic dust. If all these matters enter the flask when the seal is broken, we are not certain to what source to trace the life of the organisms which subsequently appear. If the spores that enter are fecund and find there a suitable soil, undoubtedly some of the life is due to these spores.

But what shall we say of the minute particles of organic and organized tissue which

also entered through the broken seal? Are they impotent? These experiments are, and from the start have been, undertaken to find out whether organic and organized tissues were impotent to produce fermentation and putrefaction, or whether out of them could arise new beings devoid of parents. If now, when we have arrived at an *experimentum crucis*, we pass into the flask organized tissue together with the spores, and then say it is the spore which produced the subsequent coming life, and the organized tissue had nothing to do with it, we might as well have left the experiment undone. Such an experiment is inconclusive and quite beneath the acute mental perception of a man like Claude Bernard. It is a wonder the French Academy listened to it.

Mr. John Tyndall modifies this experiment, and it becomes apparently more demonstrative to his mind. This able experimenter constructs an air-tight box with a tightly-fitting door. At both ends he has a small window; in front a large pane of glass. To his audience at the Royal Institution he explains this closet, and, darkening the lecture-room, throws a pencil of rays from an oxyhydrogen light through the two end windows. He calls attention to the minute particles floating in the air, which become visible in the ray of light within the closet, as do the motes floating in the sun-beam in a dark room. After the door of the box has been closed, and these particles have settled to the bottom, he again flashes the ray of light through the windows, and shows that the ray is no longer visible, since the minute particles which reflected the light from their surfaces have subsided to the bottom. Now, to complete his experiment he introduces, through previously prepared openings in the bottom of the box, a number of tubes with open mouths, filled with culture-fluids. The contents of these tubes he exposes thus to what he is pleased to call a pure germless atmosphere, and the contents of the tubes remain without signs of life. But he then opens the door of the box, and it becomes flooded, as he says, with the germs and spores of lower organisms, as he demonstrates again by the ray of light, which fairly dances when the door is opened, like a sunbeam in a dusty room. He believes, and has persuaded many others to believe, that he has materialized the supposed spores, and, with a little imagination to aid us, we see them, almost handle them, as they enter the culture-tubes. And his culture-tubes, previously inert in germless air, soon become filled with abundant life.

This experiment of Tyndall's would be very conclusive, also, were we sure that the motes floating in his ray of light are spores of lower organisms, and nothing but spores. Whereas we are positively sure that there are other things, some of them at least organic, in abundance, and are not at all sure that he has shown us, with all his ingenuity, even a single spore or fecund seed of a lower organism. He has never proved that such spores floating in the air are able to reflect light and become visible in the ray of light transmitted through his closet. In fact, these spores are so infinitely small it is impossible to suppose that they can be rendered visible in this manner. Tyndall, so far as we actually know, might have the air of the closet solid with spores without the ray of light discovering their presence or rendering them visible. This experiment, literally interpreted, would lead us to believe that the lower organisms found in the culture-tubes derive their origin not from pre-existing spores but from the dust floating in air; in other words, that their spontaneous generation was probable, and that they might be beings arising *de novo*, devoid of parents.

Such experiments are mere idle trifling with the real question in hand,—mere tricks of a prestidigitateur. Tyndall seems to stand before his audience like a juggler. In one hand he holds a culture-tube containing a sterilized fluid; with the other hand he gracefully catches his spore, claps it into the tube, and, presto! with the tap of his wand the spore has germinated. The majority of the audience trust him as they do the juggler, that he did what he said he did,—put in only a spore; while others think that the success of the trick depended on the other things put in, and are not at all sure there was any spore present.

I have reserved till now the consideration of the boiling, so much insisted on. All the experiment fluids are what is called sterilized, which means that they have been boiled for an indefinite time. This is done to kill the spores in them. In my course of lectures on the Germ Theory of Disease, before the Lowell Institute in Boston, I objected to the boiling process, simply because by this procedure we cut ourselves off from ascertaining the power or force residing in living tissue. Needham claimed that organized tissues possess certain powers, one of which is to transform themselves into lower orders of life. This he called the vegetative or productive force. This force displays itself during the transition of the tissues from life to complete death or dissolution. Long-continued boiling annihi-

lates this power, and deprives us of the opportunity to estimate this force. The urgency for boiling is very strong in the minds of Pasteur and Tyndall and others, because, as they say, the organized tissues are full of the spores of lower organisms. Of course, no experiment is a fair one if the materials used for culture-fluids contain pre-existing spores. Koch, however, denies that the normal tissues contain lower organisms or their spores, and no one by microscopic examination has demonstrated their presence. Nevertheless, granting, for the sake of argument, that some spores of lower organisms do exist in healthy tissues, it must be conceded by all that the tissues of our body are not made up solely and entirely of such spores. There must exist portions of tissues which are not composed of spores. Now, we know the capacity of the spores: they will reproduce their like. What we are trying to find out is what the tissue will do,—tissue devoid of spores, tissue unboiled and in possession of this vegetative force. This is the problem before us in fermentation, putrefaction, and disease, since in nature things and tissues are not boiled.

A critic of my Lowell lectures, while acknowledging the potency of living organic matter, blundered, as have all the others, in some experiments for testing its inherent power or force. He took healthy blood with all possible precaution, and then *boiled* it. Does he suppose that boiled is the same as unboiled blood? Is the potency of ambient living matter the same after boiling as before? Is a man unchanged in his potencies after being put into a tank of boiling water? If he believes that no change has been effected by boiling, then his experiments are fair; if any change has been effected in the blood, then his experiment is not fair.

Let us perform the experiment in a different manner: Take a piece of flesh from a living animal, say from a healthy man whose limb is to be amputated on account of an injury. The part must be protected from the air by thick layers of cotton-wool as completely as Pasteur protects his culture experiments, and be placed in a rigidly cleaned flask. Do everything which Pasteur does except boil it. What happens? If sufficient heat and moisture are present the flesh decomposes and swarms with minute moving particles, which are called lower organisms, or microbes,—the microbes of putrefaction. But the critic exclaims, This experiment will not do, because the flesh has in it the pre-existent spores of the lower organisms. Has

any one shown the spores in such flesh? I do not want to use the flesh if it has such spores in it, but I am not willing to kill the living flesh by boiling for the sake of destroying the spore which is only supposed to be present. The critic says he may be unable to show the spores in the flesh by the microscope, but will undertake to prove their presence in another way, viz., by growing organisms. If an organism appears there must have been spores present, so he says. Here we arrive at the same position again. The critic is convinced of the relationship of spores to organisms, because of his formula, *omne vivum ex ovo*, but he has adduced no proof from his experiment with boiled flesh or blood, because by boiling he has destroyed the vital condition of the flesh in which it can produce organisms, just as freely and abundantly as pre-existent spores can.

If the critic is discontented with healthy tissue, without boiling to kill the spores, for this trial, he ought, if he is fair-minded, to be dissatisfied with the test with flesh after boiling, because he then has to do with dead flesh. The cook in the kitchen could have told him that boiled flesh, with its adherent spores and vital tissue both destroyed, would keep if sealed up. What we want to know is what the vital—that is, unboiled—tissues of our bodies devoid of spores are able to do. If such tissue cannot be obtained the question must remain undecided, because, let it be repeated and remembered, we gain no information from boiled tissues.

Cannot some sporeless tissue be grown, an animal or plant, which has never been defiled with the contact of a microbe of putrefaction? Such tissue could be tested, with fairness, *without boiling* to see if it would putrefy and swarm with organisms. Let me suggest a method of obtaining such an animal. We have all heard of pure cultures of lower organisms. Pasteur's theory of disease-production depends on this method. Pure cultures of lower organisms are obtained by planting, taking the matters containing lower organisms or their spores in culture media suited to their development and growth. From the first culture there is transferred some of the growing organisms to a second, and so on in continuous series until even a hundred generations have been developed. The process is supposed to remove, in the first place, all other organisms, and, secondly, all foreign matters, leaving merely the cultivated organisms. The culture is called pure, because no other organisms are present save

the one desired. Could not a "pure culture" of rabbits be obtained in the same manner? Here is an entirely imaginary experiment. Take a series of a hundred air-tight cages, properly arranged with openings for admitting air and passing in food. The air must be filtered from germs, and the food boiled to destroy the spores. The newly-born rabbits can be transferred from one cage to another by forceps or wires which have been properly sterilized. The hundredth lineal descendant of the original rabbit ought to be as "pure" as the hundredth culture of a microbe, if the work is properly done. There need be no more exposure of the successive crops of rabbits to air-contamination than occurs in inoculating the culture-flask with platinum wire when the plugs of cotton-wool are removed; the forceps or wire for transferring the newly born rabbits from cage to cage can be heated to redness, as is the platinum for inoculation of the culture-fluids, to destroy the spores which stick fast to them. (This heating of platinum wires is part of the legerdemain; I am willing to heat platinum wires to whiteness, if any one will show a spore on such a wire, but I am not willing to deceive myself and others by participating in a trick and calling it a solemn necessity. If there is necessity for heating the wires at all, they should be kept red-hot all the time. After leaving the flame, while passing from the lamp to the culture-flask, and from one culture-flask to the other, the air-spores might alight on the wire, and, horrible thought! contaminate it. To be sure, if the wire is red-hot, the cultured organism will be burned to death, but if the redness is not maintained, contamination is threatened; either way the liability to error spoils the certainty of the experiment.) Here is the way out in regard to the boiling difficulty and the sporeful tissue. Take the hundredth generation of rabbits, kill them by drowning in a sterilized beef-tea, maintain the temperature and the supply of sporeless air, suited to putrefaction. Does any one believe for an instant that those rabbits, thus undefiled by pre-existing spores, having been fed on germless air and sporeless food for a hundred generations, will not putrefy? Does any one think they would remain unchanged forever? If they did, they would form a "monument more lasting than brass" to some future Pasteur. Let no one suggest boiling the rabbits. The necessity for it has ceased; the spores do not exist, and the tissue we do not want killed by boiling it. And now we are in a position to

know what organized tissue devoid of spores can do. Can it or can it not, through its vegetative force, produce the lower organisms, so called, devoid of parents? Can it ferment or decompose without the aid of extraneous microbes?

Who can do this piece of work? It would take a considerable establishment, backed by great wealth, with a corps of assistants, and a judicial-minded, skilled investigator to direct it. The superintendent must not have prejudged the case, he must not start to find proofs that lower organisms cannot arise spontaneously. I know of no one who has the skill, the appliances, and the pecuniary support except Pasteur, but he is lacking in the most essential thing of all,—the open-mindedness. I should be loath to trust the matter in his hands. But until this work has been done we shall not settle the question of spontaneous generation, or know the power or force which exists in our tissues in respect to disease.

Pasteur next turned his attention to the fermentations and putrefactions. On the basis of his studies in spontaneous generation, which had taught him—inconclusively as we have just seen—that no power or force resided in the tissue, he formulated the exclusive theory that no fermentation or putrefaction could take place except from the vital action, the growth of a lower organism. He concluded that, as boiled organic matters were stable until he introduced a fermentative or putrefactive organism, the changes taking place in unboiled matters were due exclusively to these organisms.

I do not question the fact that lower organisms exist in fermenting and putrefying matters; it is their *exclusive* origin from spores which has just been disputed; neither do I question that lower organisms growing in fermentable matters produce certain effects.

The questions which have not been settled are, whether organic and organized matters, other than lower organisms, are in nature in a state prone to decomposition, and are capable, if brought in contact whilst in this natural state, with other organic matters in a stable condition, of communicating a fermenting power or force to such other materials. I question, also, whether Pasteur has shown with entire certainty that the action of the micro-organisms which are present in fermentations is exclusively a vital one.

And to determine this question, it is necessary first to define what is meant by vital action. When an oak-tree is growing in the

forest as the micro-organism grows in the brewer's vat, the tree is abstracting from the soil certain elements necessary to its growth. The removal of certain ingredients from the soil introduces a chain of changes which would not take place unless these ingredients were removed. These ingredients can be abstracted by other means than the growth of trees, and similar changes in the soil will ensue. Hence these changes of the soil are not to be regarded as vital changes, and are by no means to be regarded as necessarily connected with the growth of the tree, since such changes can be effected by other means. The vital changes commence only within the tissues of the organisms. So with respect to man: the purchase of meat is not a vital change; those only are vital changes which take place in the repair of the bodily tissues. The depletion or stagnation of the meat-market cannot be looked upon by any one as a vital process. Vital action, then, is such as is directly concerned with vital changes.

Let us look at some very simple and familiar ferments and fermentations. Every one knows something of pepsin and of its action on certain ingredients of our food. The process is so familiar that it is unnecessary to relate it. Can any one show that this ferment's action is due to a lower organism, to a microbe? It clearly is not, and so furnishes a single exception to Pasteur's law, which breaks up his exclusive theory of fermentation. Here is another instance: take a rich solution of sugar or of beef-soup; let the fluids be thoroughly sterilized by continuous boiling until entirely stable, so that indefinite keeping shows no alteration in them. They must be used when fresh, else they insensibly suffer change (to which the name of fermentation has been denied), losing the original characters. Now take your own finger,—this is *not* an imaginary experiment: it has been done,—thoroughly cleansed by means of any or every possible precaution, save that it must not be boiled to sterilization; stop short of that; then place it in the solution of sugar or beef-soup, being careful to admit no spores of lower organisms from the air. After the finger has been kept in the solution for some time, say until the skin begins to bleach, remove it and place the solution in a warm place. What will happen to it after a time? Why, it will rot. The word rot is used advisedly to express collectively the process found to take place in all the fermentations, decompositions, and putrefactions,—use what term we will to express them, as they are all similar, varying merely

in the matters present and the resulting products, and also—as Pasteur would affirm—in the organism which is on hand. And his statement we may credit without believing in the vital necessity of that organism. Does any one affirm that the action of the finger on the sugar solution is a vital action? Certainly it is not so in the sense Pasteur would have us believe that his microbes have a vital action or in alcoholic fermentation. But then it is quite probable that Pasteur does not understand what vital action is. He may have mistaken another sort of action for vital action.

How is the action of the finger on the sugar solution to be explained? If one examines the solution microscopically, one finds in it particles of the outer skin, which, alive when placed in the solution, separate from the skin and float off into the liquid, dying but not dead, only on their way to death and disintegration. These particles being in a state of unstable equilibrium, ready to disintegrate with the heat and moisture, communicate their unstable state to the solution, which had been rendered stable by prolonged boiling. In the solution rendered unstable by the introduction of a pure, clean, but unstable substance, the finger, we have exhibited a certain process. This process differs from Pasteur's fermentations on account of the different agent employed to start the process. The process, however, is of the same nature as his, and is certainly not a vital process, neither is it due to a lower organism.

One word in regard to the method of cleansing the finger. I have said that every precaution was allowable to render the finger clean. The experiment can be readily spoiled and the brilliancy of its teaching marred by the way the cleaning is done. Cleaning is now generally effected by antiseptic agents. Suppose it to be done in the experiment by corrosive sublimate; the corrosive sublimate must be removed from the finger; none of that substance must go into the solution of sugar. Nothing else is wanted to test the merits of a sugar solution and a finger but sugar and a clean finger. This condition of cleanliness towards corrosive sublimate and everything else must be particularly insisted on, because corrosive sublimate prevents every fermentation.

Here is another experiment which it is desirable that Pasteur should try. It contains a vast amount of instruction, looked at from the proper point of view. His theory is that the changes seen in fermentation are due to the vital action of the lower organisms on the

fermenting fluid. Could he not grow some pure cultures of the lower organisms connected with a particular kind of fermentation, and then take a handful of them and place them for an instant in the solution? Or, as perhaps the instantaneous immersion would not be needfully long, could he not arrange the flask so that the organism should grow not in the fluid, but in the air on a shelf above it, so placed that the surface disintegrations from the growing fungus—the leaves and bark, as it were, of these little vegetables—would fall into the fluid? By an experiment arranged in this manner Pasteur would be able to tell us whether the fermentation was the result of vital action, or came from the power communicated to the sugar solution by the dying disintegrating particles of the fungus dispersed through it. Until he has told us this, and clearly made apparent this distinction, his theory of fermentation is not worth the paper it is written on. This method of performing the experiment brings it in conformity with the trial of the finger, sugar, or beef-soup solution, and Pasteur will find the result to be the same.

The experiment can be made in another way. Take a piece of tissue, say of liver, kept in a preservative solution in which it will remain indefinitely without change. After a time start a mould to grow in the upper part of the flask in which the specimen is kept. As the fungus dies the disintegrating particles drop down, and coming in contact with the preserved liver, start in motion its hitherto stable constituents, and the disintegrating or rotting process extends to it. Doubtless Pasteur would reject such a method of trial, because, forsooth, the liver had not been "rigidly" enough boiled, or perhaps because it would militate strongly against his theory,—and it is not pleasant to have a theory upset which one has proved so carefully.

The question of fermentation is the reverse one of spontaneous generation. In the latter, organic materials are sterilized by boiling to see if they are then able to originate organisms *de novo*; in fermentation, organic materials are sterilized and then inoculated with an organism to induce a fermentation. Each of these experiments involves an error: in the one is first destroyed the force capable of generating a new organism, in the other the inoculation is made with organisms floating in or mixed with other matters in a state of unstable equilibrium, since it is impossible to separate the organisms

from the matter and introduce merely the organism to the sterilized fluids, and hence we are unable to distinguish which of the two—the organism or the unstable matter—is the real efficient agent in the procuring of a fermentation.

If Pasteur has not shown us conclusively that organized tissues (unboiled) are powerless to cause fermentation, putrefaction, and the like, why may we not believe that emanations from our body in a diseased condition are capable of communicating disease? Diseases have been compared to fermentations, giving the name zymotic to some of them. In disease the tissues of our body become altered, and are separating and being discharged by various channels more rapidly than in health. Why cannot these particles of tissue, coming in contact with another person, be supposed capable of communicating disease, as we have seen the minute particles of finger produce putrefaction in the sugar solution? Why is it necessary, or even rational, to call in the aid of bacteria or microbes? Apparently the only reason for believing in their efficiency and disbelieving in the tissues is that Pasteur has proved that *boiled* tissues are inert. (But these tissues are unboiled.)

How is disease communicated? In contagious diseases, so far as we know, the emanations of the patient, carried by various methods, are transmitted more or less directly from the sick to the well. It is not necessary here to speak of non-contagious or non-infectious diseases, such as gout, because no microbe has been displayed for them, although, for complete consistency with Pasteur's theory of fermentation, bacteria are as necessary for them as for anthrax disease or smallpox. These emanations consist of minute particles of diseased tissue, which float in the air or are in drinking-water, or adhere to articles of clothing, and they can be traced in their departure from the diseased, in their passage and in their arrival to the healthy. These particles of tissue have not been boiled, and why should we not believe in their efficiency for the communication of disease?

Particles of tissue have a very high potency of known character. Look at the pollen of the flower. Look at sperm-fluid coming in contact with an ovum. The pollen and the sperm are particles of tissue not entitled to be called organized, merely organic, separating from the parent organism, desquamating, dying, and on their way to death, but not dead; incapable of sustained separate existence,—and they are not lower organisms,

bacteria or microbes,—and behold their power! They possess the greatest power in nature. Can we not believe that a piece of tissue from a smallpox patient, if it has not been boiled, is gifted with at least a minimum of force? Again, if we take a rasping-file and grate off a fine dust of particles of skin over an ulcer that refuses to heal,—it is not necessary to cut out the thickness of the skin or draw blood. Dandruff will hardly suffice; but the mere surface epithelium, which will depart from the skin at the next hand-washing, will serve,—and behold the growth of skin on the ulcer from the planting of such small particles, which we look upon as nearly dead. Can we not suppose that the diseased skin separating from scarlet fever can communicate the disease to the healthy?

This is a show of power, of force of just the sort we are searching for in the communication of disease. Why should we even think for a moment about Pasteur's or anybody else's microbes? Apparently, the answer comes again, because Pasteur has shown that boiled organized tissues are stable, and will not originate a fermentation.

What evidence has Pasteur to offer for his microbe? His proof rests on the artificial production of disease in the lower animals by inoculation experiments. It will be necessary to examine his methods, for he starts much prejudiced in favor of this little vegetable organism, and against organized tissue; in fact, he is ready to hand over the whole of nature to the masterful influence of a microbe. Practically his method of work consists of the same means which he employs in fermentation experiments: merely that he substitutes for the sterilized fermenting fluid an animal into which is introduced the bacteria or microbes. He gets his microbes from the blood or tissues of a diseased animal, and puts a minute quantity of this blood, supposed to contain the microbes, into a sterilized culture-fluid in which, after many trials, the microbe of this disease has been found to grow the best. A portion of this culture, say a drop, is transferred to a second culture-fluid, and this in continuous series for an indefinite number. The final culture is called a pure culture. Just how many transferences or successive crops must be made to arrive at a culture which can be called *pure* neither Pasteur nor any one else has determined. Whether it is the sixth or the sixtieth flask which affords purity no one has shown, or whether the number of cultures differ in different microbes. Each experimenter has stopped his

cultures according to his own fancy, or sometimes when objectors stopped objecting, but as yet the criteria of purity remain uncertain. Some have called the culture pure when no other bacteria can be found in the culture-material save those considered characteristic of the disease.

Let us see what should be the criteria of purity. What is it we want to get rid of? Free from what must the material be to be considered pure? It can hardly be that all these successive cultures should be made merely to free the drop of blood of another organism than the one desired for use. In fact, if the theory which has arisen from all this elaborate work be true, but one organism can be present; if two organisms exist in the blood, there ought to be two diseases,—a disease for each organism. If it is freedom from the tissue that is sought by the culture method, then a lingering doubt exists that the organized tissue may have some force and some power to communicate disease. How is it supposed that the cultures rid themselves of the animal tissues? Pasteur has claimed, or others for him, in his experiments with liquid cultures, that the dilution of the blood by the successive transferences was all that was requisite to rid it of all traces of the original tissue. He has shown that commencing with a single drop of blood, and using each time a given quantity of culture-fluid, and transferring each time a single drop from one culture to another, in twelve successive cultures there is the same dilution of original blood-drop as if it had been placed in a bulk of culture-fluid as large as the earth we inhabit. Such a dilution is so immense, so beyond our conception, that it would seem entirely sufficient for the purpose. Pasteur has contented himself with dilutions less ample as affording the requisite purity. Is the idea intended to be conveyed in this mathematical calculation of the dilution a correct and fair one? I think not, because there are two important factors omitted from the mathematical expression, viz.: the question of the propagation of an influence by the morbid tissue and the time occupied by the process of culture. These two points are very important ones, and to them the attention of criticism has not been previously called that I am aware of. Pasteur, to convince us that his dilution is all-sufficient, speaks as though he had arranged in a row the twelve culture-flasks, into the first of which he places the drop of blood, shakes the flask to mix it thoroughly, and then takes

a drop of No. 2 and mixes it with No. 3, and so on with all to No. 12. This would be a fair dilution to the extent he calculates, and the mixture would be effected within twenty minutes. But he omits to speak of the time occupied. In reality No. 12 may not receive its drop of blood for a month or more, because of the pauses made for the culture to be effected in each successive flask. What happens in these pauses? Does anything else take place but the growth of the bacteria? Can anything else be supposed to be happening simultaneously? This culture process is undertaken to show that the original morbid tissue has no influence, and we are questioning whether this method furnishes conclusive proof of its want of power. If the tissue or blood has a morbid power of propagating disease, may it not communicate this power to the culture-fluid and propagate it through an endless number of flasks of fluid, if time be given for its influence to be exerted? If so, the dilution which Pasteur calculates as so enormous is misleading and delusive.

If Pasteur will make the actual dilution he describes, drop the blood into an ocean the size of the earth, and take a syringeful of the mixture for injecting an animal, he will find that not one of the microbes from the original drop will turn up in the syringeful of fluid. The whole question is in respect to the ability of morbid tissue as against microbes to propagate an influence and communicate disease, and the dilutions as performed by Pasteur, with pauses for this influence to be communicated to the culture-fluid, do not prove that this power or influence is eradicated or lessened by the dilution, no matter how great. Dilution of a drop into the ocean will eradicate this power, just as it causes Pasteur's microbe to disappear wholly and completely. Hence we are not certain that the culture method gets rid of the influence of the morbid tissue of the diseased person or animal. Some would say, What about this morbid tissue? We believe (or have believed) that disease is communicated by a *virus*, that so much and no more virus exists in a given bulk of tissue, and that Pasteur's culture method is sufficient to dilute or eradicate this chemical virus. It would be well to give up the use of this word virus. It does not mean anything, and nothing is known about it. It was invented by some poetical gentleman as a cloak for our ignorance. He knew nothing of the way disease was communicated or produced, and he com-

pared the cause to a poison and called it a virus. He never saw it, handled it, or knew anything of its nature: merely supposed it was a chemical compound. A virus can be diluted, while the morbid influence of tissue cannot be eradicated by culture. Let us not mention the word again. Disease is not like a poisoning; typhoid fever in no manner resembles a snake-bite, or morphine- or arsenic-poisoning. The two cannot be compared. Neither is disease like a fermentation. The word *symotic* is a mere figurative expression, which serves well in board of health schedules, but otherwise is misleading. It does not behoove the germ-theory advocates, who advance the vital action of bacteria in disease, to speak of ptomaines, the chemical poisons which these minute organisms produce, else they will find that the causes of disease must be regarded as a chemical substance,—something to be put into a bottle,—and not the vital effect of a lower organism.

Pasteur has made experiments in a number of maladies and has given us the results of his work. His first achievement was in relation to diseases of the silk-worm. The cause of the decline and death of the caterpillar was clearly pointed out, but that the condition which the author describes is to be compared with such general maladies as smallpox or typhoid fever as seen in the human race cannot be admitted. In one sense the silk-worm malady is not a disease: it is merely a mechanical destruction of the silk-worm by a parasitic fungus, which is enabled to grow by attaching itself to the surface of the worm when these silk-spinners are enfeebled by unsuitable hygienic conditions. When the worm is in healthy condition it immediately cleans itself of the parasite as it frees itself from any other foulness. A prisoner in a foul dungeon becomes infested with vermin or gnawed by rats, but the presence of the rats and vermin is not disease. The unshackled prisoner, with soap and water or a club, frees himself from their mechanical irritation.

Chicken-cholera was Pasteur's next work. It was in connection with this disease that his culture-methods were fully developed. For the first time he produced cultures of the microbes having a variable degree of virulence,—some killing the bird within a few hours, others producing death a few days or a week after inoculation. His chief work in this disease was the employment of preventive inoculations. These vaccinations against chicken-cholera have had claimed for them a great success, but the life of a chicken is so short

that it is very uncertain whether the effects of the vaccinations are permanent. It has been shown, however, that inoculations with septicæmic matters prevent chicken-cholera as efficiently as Pasteur's vaccine matter, so that it is entirely uncertain whether he ever found a genuine preventive. It is more than likely that Pasteur communicated to the chicken a mild form of septicæmia, which temporarily rendered the bird insusceptible to this disease, as we know that septicæmia renders a person rebellious to the infection of all contagious diseases. Again, it is not improbable, judging from Pasteur's reports, that this disease is not communicable by inoculation, since the symptoms produced in the inoculated bird are almost wholly unlike the conditions seen in chickens which acquired the disease by the natural method.

It is in connection with charbon or anthrax disease in animals and man that Pasteur acquired his greatest fame as an experimenter. In nearly all his observations of this malady he had, however, been anticipated by other observers. His fame arose from the proposal to eradicate the disease by the universal inoculation of every animal liable to the malady. It was the experiments with anthrax which seemed at the time to be producing a furor of belief in the germ agency of disease, and to-day one meets those who, while doubting the proof for other maladies, wonder that a doubt remains of the power of the anthrax bacillus, because, as the remark commonly goes, this lower organism is so easily found and is so abundant in the diseased animal. It seems that belief rises in proportion to the size of the microbe; with a microbe so large,—one we are so nearly able to handle, and one so easily to be seen with even a low-powered microscope,—many yield to the impression that such organisms have a potent effect.

Since these experiments have commanded such wide belief, it is especially necessary to examine the results to see if they prove precisely what they are used to prove.

An examination of the reports of experimenters on inoculations of animals with cultures of anthrax shows varying results, according to the degree of purity from morbid tissue in the culture of fluids. Commencing first by examining cases of disease acquired in the natural method, we find it is communicated from individual to individual, animal to man, by direct contact of the healthy with the diseased, or with the hides or hair taken from diseased animals. The morbid tissue is transferred from one to another, or the currier or wool-sorter has

portions of it lodge on his hands, perhaps in a slight scratch, or he may even inhale a portion. After a varying interval of time, called the period of incubation, a local sore appears at the place of inoculation. This incubation is the time required to pervert the healthy action of the tissues of the hand at the point of the scratch. Then follow symptoms, accompanied by fever, due to the absorption of the unhealthy products of inflammation, and with these symptoms are developed definite alterations of the lungs, spleen, liver and kidneys, as well as other organs. Death or recovery results as in other contagious or inoculable diseases. Pasteur says the period of incubation represents the time required for the growth of the anthrax bacillus and of its dissemination over the body by the circulation. He is not justified in ascribing the communication of the disease to the bacillus, because he has not proved that the morbid tissue that goes with it has not the power of communicating disease. He must remember that in natural contagion the carcass of the diseased animal has not been boiled to sterilization, and that the power of its tissue, greatly enhanced by the diseased state, still inheres.

Now, if we examine the results of artificial inoculations with material from No. 1 culture in the series of a dozen, we shall have very similar results. These will vary, however, with the animal used for inoculation purposes, as it is but natural to expect. They vary because in the artificial case the inoculation may be better, more effectually done; the matter used is fluid, ready to be syringed in easily, instead of a small particle of tissue, frozen and dried on its journey from Siberia, where the disease is prevalent. For these and other reasons easy to suggest, the inoculated animal has the disease communicated more thoroughly; it affects the internal organs more rapidly, and perhaps death may come sooner than in the natural case. If the culture stands a few days, giving the anthrax microbe time to increase in number in the culture-fluid before inoculation, the number of bacilli in the animal inoculated will be found greater than in a person or animal acquiring the disease naturally. But otherwise the symptoms, the changes in the organs, will be exactly the same in the natural and in the artificial disease.

This result does not prove, of course, that the disease-communicating power resides in the tissues, although the tissues were present in both the natural and the artificially pro-

duced disease. But let us look at the phenomena in an animal inoculated with the twelfth and later cultures. In such cultures it is evident the tissue has lost its power. Behold the result! The testimony of all observers seems to concur. The animal remains in apparent perfect health about forty-eight hours after the inoculation is made; then, often with great suddenness, crouches down, trembles, or, more commonly, has convulsions, which continue until death, which ensues rapidly. Are those the symptoms of anthrax disease? No, self-evidently not. Let us examine the post-mortem records of the dead animals. The reports read that all the organs of the body present a perfectly natural appearance, save that in many places, especially in the lungs, minute blood-spots, called ecchymoses, are seen. An examination with the microscope shows in the centre of these little spots a minute blood-vessel blocked with the anthrax bacilli. This blocking has caused the rupture of the blood-vessel, and the blood and the bacilli are poured out into the tissue. Hundreds—nay, thousands—of the blockages with hemorrhages are to be found, but especially numerous in the lungs. Are these the changes which are found characteristically in animals dead of anthrax disease acquired in the natural way? Again, no. What have the two results in common? Apparently only death. Can two diseases be considered for a single moment the same or in any way related which have neither the symptoms nor the alterations in the organs alike? Again, most emphatically, no. I said just now that the two conditions—inoculation with a No. 1 culture and with a No. 12 culture—have death only in common. They have also the bacilli in common, but the number of these organisms in the two conditions differs, the microbes being vastly more numerous and more concentrated in the vessels in the latter than in the former. They differ in another respect, also, viz., their cause or antecedent circumstances, and this fact is most important to remember. In No. 1 there was used for inoculation tissue and bacilli, and in No. 12 bacilli without the tissue. We have seen the difference in the result: one produces the disease, the latter produces death without the disease.

How can the result be accounted for from the bacillus inoculation with the No. 12 culture? Very readily, indeed. Into the animal we syringe a small quantity of fluid containing nothing save a richly-growing organism. During twenty-four or forty-eight hours the

microbes found in anthrax disease increase immensely in number; the few that were introduced have become millions on millions; and note especially that the animal inoculated shows no deviation in health, either generally, or locally at the point of inoculation. It eats and drinks and frolics, as it ought *not* to do if millions of anthrax bacilli can produce injury by their vital action. Suddenly the scene changes: out of perfect health panting and convulsion come. Can we find from the post-mortem examination anything to account for this sudden convulsion and shortness of breath? Pasteur says the sudden death is due to the anthrax microbe consuming by its vital action the oxygen of the blood, and the deprivation of oxygen causes the convulsion, and, as the process of absorption becomes complete, death. But what has the post-mortem examination shown us? It has shown blocks, called emboli, composed of bacilli, in half the minute vessels of the lungs. These blocks have stopped the circulation of the blood through the lungs, and consequently prevented the aeration of the blood. We know of death with similar symptoms produced by another condition of the blood-vessels of the lungs in which bacilli are not present. A woman after childbirth has one of the clots naturally formed in the uterine veins detached and carried by the blood-current, first to the heart and then to the lungs. When the clot blocks the vessels of the lungs, the woman, from a condition of perfect health, passes into convulsions, and with panting respiration dies very quickly. The symptoms and the post-mortem examination show precisely the same conditions in the animal inoculated with a pure culture of anthrax bacillus and the healthy woman in childbed, save in the former the occlusion of the blood-vessels is due to collections of anthrax bacilli which have lodged, and in the latter the blocks are composed of firm clots of blood. In these two instances death has no more been due to anthrax disease—or, in fact, to any other disease, as the word is ordinarily used—than in the case of a man on the scaffold with a rope around his neck. They are all instances of strangulation. The man's death we know all about, for we are familiar with ropes. The woman's death is more recondite, but entirely simple to those familiar with such conditions. In the inoculated animal we are not prepared to believe that anthrax disease has been communicated because we are shown a dead animal and the bacilli.

One word is demanded to explain that the

capabilities of the anthrax bacilli of killing in this manner are possessed by this microbe alone. The anthrax bacillus has a length greater than any other lower organism found in connection with internal diseases. Its length exceeds the diameter of a red blood-corpuscle; hence all goes well when they are carried endwise in the blood-current, like logs of timber carried down-stream; but in the fine capillaries, which can carry only a single red blood-corpuscle, let an anthrax bacillus become turned crosswise, and immediately a jam, as of logs in a river, takes place, the bacilli become piled up, and the blood-vessel ruptures and causes a minute hemorrhage. On account of its superior length the anthrax microbe alone can furnish such an incident and produce, when in sufficient numbers, this sudden death. Hence the brilliancy of Pasteur's results,—sure death to the inoculated animal,—together with the readiness of displaying the microbe, has gained him many believers.

In respect to his preventive inoculation of anthrax disease, we cannot stop to discuss his juggling to prepare the vaccine matter, which used to be offered for sale by the kilogramme at Boutroux's shop, Rue Vanquellan, 18, Paris; it must suffice to say that it is an easy deception of observation readily explained. Whatever else is done in preparing the vaccine material by cultures, it is evident from Pasteur's own claims that the virtues have so far departed that the disease itself is not communicated; it is also true, if his own theory is to be trusted, that a rotting fluid is prepared,—using the word rot in the broad sense, decomposed in some manner by the growth of a microbe,—and this rotting fluid is used for the preventive inoculation. The expected conditions follow; a mild form of septicæmia in the cattle is caused, rendering the animals "refractory" to the influence of the contagion of anthrax. Pasteur will find his animals equally protected against the smallpox or scarlet fever or any other contagious malady to which they may be liable. Man is not likely to contract smallpox or other contagious diseases while suffering from septicæmia. Septicæmia is a more sure protection from contagion than the contagious diseases are against each other. Measles and scarlet fever, and other eruptive diseases, may follow each other in rapid succession, or may coexist even, but septicæmia while it exists, and for long after, bars out other maladies of a contagious sort. But Pasteur does not seem to recognize these facts any more

clearly than he comprehends that his preventive inoculation is a septicæmic condition. Why should we expect him to? He is not a physician, much less a pathologist. Why is it not more than likely that he should be self-deceived by his experiments? Further, the inoculations are protective for only a few months. When the septicæmic condition of the animals passes over, they are liable to the disease as markedly as before, and so the whole matter has been given up.

The next group of diseases, for which proof has been offered of their causation by microbes, is the surgical infective diseases. This work finds a prominent representative—and at every step other observers have rendered contributions of an important character—in Dr. Koch, of Berlin, who has since made us acquainted with his studies in tubercular disease, and more recently cholera. With these diseases, which include septicæmia, pyæmia, and erysipelas, it is difficult to discover on what grounds the proof of their bacterial source is founded. It is not contended that the maladies are specific contagious diseases in the sense that smallpox and scarlet fever are. One case does not presuppose an antecedent attack of disease in another person, although such may be. The cases originate *de novo*, and do not have to be transmitted through a continuous series. Their nature is infective, and they arise principally from or through neglect or uncleanly conditions of wounds, although they may acknowledge another source.

The variable or *de novo* origin of these diseases has been taken advantage of by observers in studying their cause and nature. The experiments are begun by injecting into the tissues of animals putrid meat infusions. From animals which die of the putrefactive infective disease portions of the fluids or tissue are taken and inoculated into another series of animals, and so on, with the result, which is not at all surprising, that the virulence of the infectious matter is increased, and death follows the inoculation with greater and greater rapidity.

It is at once very striking that this method of study differs *in toto* from that in other diseases. In all the others the aim has been to arrive at a pure culture of the germs or microbes. Why is this difference? No explanation has been offered, and yet it would seem we are equally in these diseases entitled to see, to study the action of the pure culture of organisms, apart from the effects of putrid tissue, as in the other maladies. Nay,

is it not far more important, since infective diseases are not specific, but can be generated from perfectly indifferent substances, such as putrid meat? Hitherto we have believed that wound infection was due to the absorption of the putrid discharges derived from the rapid breaking down of tissues; and now, as the result of these experiments, using for infection putrid meat,—and the organisms in it,—we are invited to believe that the efficient cause—the *causa causans*—is the organism alone, and that putrid tissue has nothing to do with the result.

I do not see how it is possible to attain to a pure, that is, a clean culture of these organisms. If the function of the microbe is putrefactive, the hundredth transference in the ninety-ninth culture-flask results in putrefaction of the culture-fluid, just as surely as this process is going on in the original putrid meat infusion. Injection of putrid culture-fluid teaches us no more than putrid meat infusion. In both cases two things are injected, a putrid tissue and certain organisms; and the question still faces us, Which of the two causes the disease?

The argument which the Germ Theorists have been pleased to put forward runs as follows,—the argument holds for this group of diseases as well as for the others: "I discover the microbe, I cultivate it, I inoculate it, and I reproduce the disease" (*Trelat. Soc. de Chirurgie de Par.*, 21 Oct., 1885). One portion of this argument without all the others does not lead us to any conclusion, and the mere finding of an organism in the dead or living tissues of disease furnishes not an atom of proof; nay, not even a probability or a possibility that it has anything whatsoever to do with the production of disease. A great deal has been written about organisms being "constantly present," or being "characteristic" of a disease, and, in fact, quite too much has been said. So very much depends on how one is looking for organisms. Has the search always been made in the same manner? Have all sorts of methods been used to discover all varieties of organisms? Or has the organism been called "characteristic" to meet the observer's wishes? Reviewing the history of organism in disease, we shall find that three other organisms have been pointed out in tubercular disease besides the present reigning one, Koch's tubercle bacillus. Pasteur has presented to the French Academy three different microbes as the genuine cause of hydrophobia. These several organisms have been in turn

abandoned in favor of the newly-discovered one, and we seem to be in daily dread of a new announcement, a new introduction which may upturn our settled convictions. The abandoned organisms do not disappear; they can be found by looking for them. The discovery of an organism does not present anything "characteristic" for the disease, in fact it gives us nothing but the opinions of some one or more observers, and we may be only on the brink of the invention of a new microscope to see a new bacillus hitherto invisible but equally constant with the present one.

The cultivation of the organisms—the second factor of the argument—we have seen; we know the process, and know what it amounts to; we have seen that it is carried on to produce purity; we have seen the uncertain standard of purity. The method may furnish us with microbes of one variety, but it never gives us purity; it never gives us singleness. We always end with using two things in inoculations, the microbe and the culture-fluid, and we shall never know to the end which one of the two produces the result. If it were possible to impale a microbe on a needle, to wash it under the faucet and rub it dry with a clean towel before inoculation, we should then know what the microbe was able to do when growing in our bodies. By this means we should see if its growth were able to cause the symptoms and the post-mortem appearances characteristic of the disease. We should have placed before us the genuine effects of the growth of the low organisms, and we should have purity, genuine purity, in our culture. As it is now, we know no more than if we took a retort with a piece of copper in it and poured on it a mixture of an acid and alkali and said, Behold how the acid affects the copper! To-day we are doing a parallel piece of work with the inoculations. We inoculate with microbes and the culture-fluid in mixture, and put the whole result down to the credit of the microbe.

Again, in judging of inoculations, a result which satisfies one observer that he has reproduced the disease does not convince others. Many conclude, when they succeed in killing the inoculated animal, that the death shows a sufficiently evident result; this is especially conspicuous in Pasteur's works; the death seems all-sufficient. Many experimenters have employed in their inoculation animals which are not susceptible of the disease under any circumstances. How can any faith be placed in their results?

The question of tubercular diseases is a most interesting and important one. Koch, of Berlin, has been the chief to formulate the germ-teachings—in fact, the discoverer of the bacillus—of this group of diseases, but a whole host of experimenters have repeated his observations. It seems almost impossible to point out, in less space than a volume, the fallacies or lack of proof of these observations, and quite hopeless to make all the objections to them clear in a few paragraphs.

In 1865, when Villemin showed by experiments that it was possible to cause tubercles to appear in animals inoculated with certain degenerating organic matters, the general opinion held at that time was that tubercular diseases were occasioned by these same materials originating from a variety of conditions within the body of a person or animal attacked by tubercle. The passing strange part of Villemin's work was that the inoculation of foreign matter served the same purpose in causing the disease as the matters occurring naturally within the body. Villemin's observations were repeated by other experimenters in a great variety of ways, and were in the main confirmed. But another important fact was shown by the experiments of others which Villemin did not discover. Villemin claimed that only tubercular matters could communicate tubercular disease to the inoculated, and that therefore tubercle was a specific disease, since like produced like. But his imitators showed that unlike, dissimilar, and even indifferent organic matters were capable of producing tubercular disease in the inoculated animal. A lump of cheese was found by many experimenters to be just as effective in producing tubercular disease as a piece of tubercular lung when introduced beneath the skin of a rabbit. In other words, any degenerating inflammatory product was liable to produce tuberculosis, and therefore the disease is not truly a specific malady, and although like did produce like, unlike matters could also produce it. Here the matter rested. The question at this time did not stand in relation with the germ theory of disease, and very rash would have been considered the theory to announce that consumption was a contagious malady because it could be inoculated.

Before the introduction of Koch's bacillus of tuberculosis there had been, as has already been mentioned, three other organisms observed, which were handed around Europe for inspection and vaunted as the genuine cause of tubercle, but, because of the minute care

which Koch had observed in his experiments, his bacillus was at once accepted as the only genuine.

And now, if this bacillus was to be accepted as the cause, it became necessary for the eminent pathologists who had found cheese efficient for the production of tubercle to explain the discrepancy. A few, Cohnheim among the number, suggested that the cow furnishing the milk for the cheese was probably tuberculous. No one ever showed the presence of bacilli in cheese; in fact, cheese manufactured in the ordinary way could not have bacilli in it: they would be destroyed; nevertheless the argument was made with seriousness. Others concluded that the results from cheese were due to bacilli, accidentally floating in the air or adhering to the knives and forceps, inoculated along with the cheese. And to remove this accidental contamination of the cheese they repeated the experiments with all due precaution. What were these precautions and how did they affect the result? They were the usual antiseptic surgical means, consisting of the use of carbolic acid spray and solution in which the hands and instruments and the wound are washed (I don't know whether the cheese was soaked in it or not, but it ought to have been, according to their theory, if it was not). Now, having inoculated the rabbit with a great deal of carbolic acid and cheese, they came to the conclusion that cheese was inert: that it never did or could produce tubercle. What a sorry piece of evidence to offer! Suppose Koch, when inoculating rabbits with pure culture of tubercle bacilli, was to do it in an atmosphere drenched with carbolic spray, his hand and instruments dripping with carbolic solution and the wound of inoculation flooded with it, would he expect his bacilli to live through such a flood and cause tuberculosis in the animal? He never allows carbolic acid to come near the bacilli, and if he did he would have negative results. No, it is the same old fallacious method of dealing with the question. Start out with the notion that lower organisms are the only genuine cause, and living tissue (or cheese unboiled) cannot possibly have any effect, and an endless number of experiments can be arrayed to favor the view. Do everything to favor the microbe, and do everything to render the tissue inert,—boil it, flood it with carbolic acid or corrosive sublimate, give tissue no chance at all,—and you will arrive at the same conclusion. Use cheese or other degenerating organic matter without bacilli and no carbolic solution, and you will have a different

result. Do not kill the bacillus (and the cheese along with it) before you catch it, or else try a boiled bacillus as well as a boiled cheese, and see where you will come out, since either both should be boiled or neither.

It is therefore yet possible that some may find a way to show the efficiency of cheese or other organic matter free from bacilli,—and there is plenty of such matter to be had,—and then the bacillus of Koch will lose its significance and importance. But let us consider the fallacy lurking in Koch's experiments. This gentleman has produced the pure culture of the bacillus in the usual manner by successive generations. The culture medium he has found necessary for the growth of the organism is a preparation of gelatinized blood-serum,—a solid medium instead of the fluid. These cultures are called pure, as in other cases, because no other organism is growing in them. But, as in other cases, the mass actually employed for inoculation consists in a considerable proportion of the gelatin, with the bacillus growing in it,—two things. The blood-serum, an organic matter previously sterilized into inertness by boiling, is passing, through the agency of the growing organism, into a state of decomposition, degeneration, rotting,—call it what you will,—and is no longer sterile, but resembles the state of cheese or other organic matters which are capable of producing tubercle. That Koch's gelatin contains bacilli is a matter of indifference. That the bacilli are mixed up with rotting gelatin is a matter of great difference, since we are thereby prevented from knowing what bacilli alone can do, unaided by a material in itself capable of producing tubercle. The reply is made to this criticism by those who do the experiments that "control" inoculations show the blood serum or gelatin to be wholly innocuous. They take blood-serum from the tube in which the bacilli grew, merely half an inch away from the growing organism. No one contends that blood-serum is noxious when sterilized, or that the serum within the tube, except as it comes within the influence of the growing organism, becomes unsterilized no one affirms. But that the serum or gelatin on which and in which the tubercle bacillus grows is no longer sterilized every one must admit, and it is this actively changing serum or gelatin which is used for inoculation. To say that blood-serum or gelatin sterilized, even if taken from the same tube with the growing organism, is harmless does not tell us anything useful,—for with the microscope,

or even with the naked eye, it is plainly evident the serum is not in the same state as that in contact with the growing organism, and which makes up the bulk of the material used for inoculation. It is probable, on the contrary, that serum or gelatin undergoing such rapid degenerating changes, induced by the growing organism on its surface, is more powerful to cause tubercular disease than other decomposing organic matters occurring either within or without our bodies; as it is thus rendered specially potent, less bulk of it serves to produce tubercular disease in the inoculated animal, irrespective of the presence or absence of the bacilli. The tubercle bacillus of Koch is but an epiphenomenon of the disease. What is wanted for use in inoculations is the bacillus alone, freed from everything else. If, again, Koch will impale a bacillus on a needle, wash it clean, and introduce it, then we shall know what it is able to do. We object most strongly to the mixture of rotten gelatin and bacilli, for the rotten organic matter we have hitherto believed to be the cause of tuberculosis.

The claims which have been put forward for the germ origin of cholera are very uncertain. Two great government commissioners have investigated and reported, and still the question is more than uncertain and unsatisfactory, and it must be very unsatisfactory even to the commissioners themselves. In fact, so little has been shown conclusively that there is scarcely anything on which to base a criticism. A majority, perhaps, of those who would admit the claim of a germ origin, were it once established for other diseases, would deny its possibility for cholera, such is the dissimilar character of the malady.

Finally come Pasteur's studies in hydrophobia. This illustrious man has made three attempts at the malady. The first essay was in 1880-81. It was a microbe taken from the saliva of a child dying of rabies after a bite from a mad dog. This was a very evident mistake, which, however, the French Academy applauded until it became quite generally known that inoculations with this microbe merely produced septicæmia. A few years later, in another communication to the Academy at Paris, another set of conclusions was presented, to be again received with favor, only to be abandoned, without disproof of any sort, for a newer theory of the distinguished savant. This last theory—the procedure under it has been officially published in the *Herald*—differs *in toto celo* from the

previous ones, and is in fact a virtual actual abandonment of the germ theory of disease. All of Pasteur's former work was to establish the fact that a microbe was the sole agent in producing disease, and, in fact, for effecting every other change in the universe.

His latest work in hydrophobia discards the micro-organism and substitutes the diseased tissue of the rabid animal. Pure cultures are thrown to the winds, and preserved spinal cords and brains, without a word of microbes, which cannot be made to appear effectively, are brought forward to do the work.

What is the method of procedure? The spinal marrow of a rabid dog is mingled in definite proportions with pure veal-broth, and this is injected into the brains of a rabbit. This experiment, Pasteur assures us, communicates hydrophobia to the rabbit. By successive transmissions from one rabbit to another the virus becomes modified, and thus fitted for the inoculation of persons in order to prevent the development of hydrophobia in those who have been bitten. In inoculating with the attenuated virus those threatened with the disease, the primary injection with the mixture of spinal cord and veal-broth is made with the weakest mixture and continued for ten or eleven successive days with a graded mixture becoming progressively more virulent. The final injection is said to be performed with a rabic virus which will produce hydrophobia in an animal or in a person unprotected by the previous injections in six days, a period shorter by one-half than the virus taken directly from a rabid animal's spinal cord would require to produce the malady, or in a very much shorter period than such an animal's bite would take to turn one mad.

In this description—and the details of the method are all kept secret—not a word occurs about the microbe; and in fact it is certain, since the spinal cord itself is employed, that the effects cannot be due to microbes alone, even supposing them to be present in the tissue. With these experiments before us one is almost tempted to believe in this item of Pasteur's work. He makes use of diseased tissue, which one could rationally suppose was able to communicate disease. That the diseased conditions reside in the nervous tissue alone we have not a single item of proof, and there is not a particle of reason to believe that this is true. Would not a piece of the tongue or a toe of the dog serve equally well? One can hardly be brought to believe that a general disease like hydrophobia is localized

in one portion of the body. Let us be rational for once.

But apart from the method of preventive inoculations of hydrophobia which Pasteur has invented, and of which we as yet know scarcely anything, the point to be insisted on in connection with our present discussion is the complete abandonment by him of the germ theory of disease. Without a microbe to look to where are we, and what becomes of that theory? If we are no longer even trying to, deal with pure cultures of organisms, but purposely include diseased tissue in our inoculation material, the theory vanishes, and we come back to the old notions, putting our faith again, as is rational and in accordance with endless testimony, in the potency of diseased tissue for the communication of disease, and in nothing else.

*FLUID EXTRACT OF CORN SILK (STIGMATA MAIDIS) IN THE PRIMARY OR ACUTE STAGE OF GONORRHOEA.*

---

BY E. STUVER, M.Sc., M.D., RAWLINS, WYO. TERR.

EVER since engaging in the practice of medicine, over six years ago, I have been a constant reader of from four to six of the best medical journals published in the United States, and always having a large number of cases of gonorrhœa to treat, have eagerly watched for every advance made in the treatment of this—in many cases—obstinate disease; but while almost innumerable remedies have been suggested, and their merits discussed pro and con, I have never seen any reference to corn silk, which, in my hands, has given such satisfactory results that I have decided to call the attention of physicians to the remedy, and ask them, after having carefully tested its merits, to report the results obtained from its use. Right here I want to insist on the necessity of using a perfectly fresh and reliable preparation of the drug, as there is the greatest difference between the physical qualities and therapeutic action of the various products put on the market, even by our most reliable manufacturing pharmacists.

I began using corn silk in irritating and painful affections of the kidneys and bladder, attended by dysuria, about five years ago, and in the *Medical News* of October 6, 1883, published an article on its "Anæsthetic and Diuretic Effects." In this article special at-

tention was called to the beneficent influence it exerts over the irritable condition, attended by frequent micturition, so often encountered in pregnancy.

Encouraged by the results obtained in the above-mentioned class of cases, I decided to test its merits in allaying the irritation and pain of the acute stage of gonorrhœa. A case soon presented itself, and the following condition noted:

C. H., laborer; contracted gonorrhœa a short time ago; discharge made its appearance yesterday; inflammatory action high, and pain on micturition severe. After giving the ordinary directions as to the regulation of diet and the alvine evacuations, abstention from spirits, etc., I gave the following, viz.:

R Potassii acetatis, ℥iii;  
Fl. ext. stigmatæ maidis,  
Aque destillatæ, aa ad q.s. f℥iv. M.  
Sig.—℥ii in water every two hours.

The following day he reported himself as greatly relieved, and under this treatment not only did the irritation and pain subside in three days, but the discharge almost entirely disappeared, and he felt so well that, against my positive instructions, he resumed his work (digging a ditch), and had a recurrence of the symptoms, which did not yield as readily to treatment as in the first instance, but were controlled, so that the entire attack did not last more than two weeks. A large number of cases might be cited, but, as they have histories very similar to the one above related, I refrain from giving them. I do not want to be understood as claiming specific powers for corn silk in the acute stage of gonorrhœa, but merely desire to call attention to it as a remedy of positive value in properly selected cases.

---

*KAWA IN GONORRHOEA.*

DR. SANNÉ recommends in the *Bulletin Général de Thérapeutique*, March 15, 1886, the kawa-plant for the treatment of acute affections of the urinary passages, especially of gonorrhœa. He gives four to ten pills of the extract daily, each pill containing  $\frac{1}{4}$  grain of the extract.

The employment of kawa for these affections does not appear, however, to be of a recent date, for Goble and O'Rocke advocated the use of this drug as early as 1860 in the same French journal.

### ANTI-PERIODIC EFFECTS OF QUININE.

SCIENTIFIC therapeutics is something like a family flour-barrel: everybody goes to it and everybody gives it a kick. Very frequently, however, the cause of the grumbling lies not with the investigator of physiological therapeutics so much as with the pathologist. In many places practical therapeutics outrun pathology, and the results which we obtain at the bedside by the use of remedies cannot be explained, because the pathologist is unable to explain the rationale of the disease.

The antiperiodic property of quinine has long been an absolute mystery, which has baffled every attempt of the scientific therapist to solve. It looks now as though the problem would be an easy one when the pathologist has done his work. The recent studies made at the Philadelphia Hospital by Professor Osler strongly strengthen the probability that the cause of intermittent fever is an infusorium in the blood, as first noticed by Thomasi Crudelli. Professor Osler has examined some forty odd cases, and, with scarcely an exception, has found the creature in one of its three forms, either as a flagellate

living body, moving about the red blood-corpuscles and scattering them hither and thither, or a quite crescentic-shaped body, or an amœboid form living in the red blood-corpuscles, and apparently destroying them.

In one or two cases in which the diagnosis founded upon the symptoms was very doubtful, Dr. Osler was able to decide the nature of the case by finding these creatures in the blood of the patient. In all of such cases quinine produced rapid amelioration. Quinine acts as a powerful toxic agent upon many of the lower forms of life, and the theory must at once suggest itself to every mind that it cures intermittent by destroying the germs to which the fever is due. We do not know of any direct experiments upon these infusoria with quinine, but certainly such studies are urgently demanded. Professor Osler has found that the cure of the intermittent by quinine is followed by the disappearance from the blood of the infusoria; such disappearance not, however, being rapid but gradual. No one has yet succeeded in growing the infusoria outside of the human body.

Although the suggestions which have been put forth in this note still belong in the category of speculation, there is enough foundation of ascertained fact to stimulate very greatly the study of the matter by those who are situated in highly malarial districts.

### BROMIDE OF ETHYL.

IN a recent number of *Science* there is recorded in detail a death which recently occurred in Brooklyn or New York from the use of bromide of ethyl by a dentist. The rapidity of action, and the general comfortableness of the bromide as an anæsthetic, leads every now and then to its being recommended by some one, and to its still being used to some extent.

When it was first actively proposed as an anæsthetic it was carefully investigated by Dr. H. C. Wood, who, as the result of his experimentations on the lower animals, arrived at the conclusions that it acts like chloroform on the heart, and that it would be a more dangerous anæsthetic than chloroform. Within a very few days after the publication of Dr. Wood's paper a case was reported in which death from cardiac failure was averted with the greatest difficulty, and only a few weeks later a fatal anæsthesia was put on record. Since that time there have

been several deaths from the use of bromide of ethyl. Those, too, in spite of the general abandonment of it.

There is probably no anæsthetic which has ever been used to any extent that has as high a mortality rate as has the bromide of ethyl. The advantages which it possesses over chloroform are so slight as to be of no importance. We do not think the habitual use of chloroform as an anæsthetic is justifiable, but certainly it is much better to employ it than to venture the dangers of the bromide.

---

#### *PRACTITIONERS AND SCIENTISTS.*

---

**I**N a brilliant review of the recent book of Mr. Whipple's, which contains the lives of Choate and Agassiz, we were much struck by the remark that the work of the lawyer is necessarily fugitive and without permanent record of fame, because he simply labors to convert his intellectual abilities into money. His work is temporary and is rewarded immediately. He builds no more for the future than does the man of business or the man of pleasure.

It is affirmed of Agassiz that he once said that he had no time to make money. This was because he was building for the good of mankind and for future generations. The best work of the world is never paid for. Newton, when he labored on his immortal astronomical papers; Keppler, when he discovered the laws which control the universe, never dreamt of pecuniary reward. The man of medicine stands midway between the lawyer on the one hand and the devotee of abstract science on the other. He partly works for money and he partly labors for the universal good, and just as he works for the one or for the other so is his reward. The fashionable practitioner, the great specialist, who annually receives his many thousands of dollars, is the man of the present. Often, however, his present success is founded upon his past labors for science, and thus it is that very few original great medical works, and very few great discoveries, very few profound researches spring from men who are past middle age. The scientific work of Charcot was done in the days of his earlier manhood. The labor of his later years goes to maintain a gorgeous palace and a retinue of servants.

American scientific medicine especially fails in its highest development on account of the ease with which men great in medical science slip over into the ranks of the money-makers.

The naturalist who for ten or fifteen years has done good work finds as he approaches forty, the age at which avarice begins to assert itself, and the demands of an increasing family grow clamorous, no new avenues open to receive him by means of which he can rapidly make money. But the American physiologist, or man great in medical science, at forty begins to see avenues leading down into new vistas of financial prosperity opening themselves in pleasant sunshine about him, and so forsaking the nobler labor of building for the general good and for the future, fattens himself in the fields of popular patronage. Thus it is that whilst American naturalists stand foremost in number as well as in greatness, American medical scientists, whose names deserve to be put alongside of those of the great men of Europe, are so pitifully few.

---

#### *CERTIFICATES TO PROPRIETARY MEDICINES.*

---

**W**E print in another column a letter from one of our subscribers concerning the giving of certificates by physicians recommending proprietary medicines. We sympathize with the views expressed in that letter thoroughly. There is no simple thing connected with the medical profession which conveys an impression of besotted weakness so strong as that produced by the certificates which are to be seen signed by men of prominence.

We are very sure that the physicians who sign these certificates are never paid for the use of their names; if they did receive an honorarium commensurate with the service which they render the proprietor of the medicine, we would have a less opinion of their morals, but a much higher one of their common sense, self-control, and business tact. The smooth-tongued, wily commercial traveler usually holds the doctor in the hollow of his hand, and moulds him as plastic clay. After his return to his rooms in the night, he enjoys most heartily recounting his triumphs of the day with his fellows.

It is very rare for a doctor to thoughtfully and carefully study the effects of one of these proprietary medicines. He gives them; the patient gets better, and he signs the certificate, receiving as an honorarium a bottle of the wretched stuff, which he in turn bestows on some poor patient. Probably the other medicines and hygienic treatment which

accompanied his gift of the sample were responsible for the good achieved, but the doctor fails to recognize this. One thing is positive, that these proprietary medicines contain nothing which may not be equally well represented in office prescriptions, and are charged for at a rate which is exorbitant. The advertising agent and commercial traveller, the medical and the lay journal management, all have to be paid out of the profits of the proprietary medicine, and the seller of this medicine deems himself a shamefully abused creature if he does not make two or three hundred per cent. clear of all his expenses.

In no section of medicine has this abuse of certificates been greater than in regard to disinfectants. There is probably no disinfectant proprietary solution prepared or sold and placed upon the market which in any way represents the price at which it is sold. Most of these proprietary disinfectants are almost inert, and the most worthless of them are those to whose certificates are appended the names of the greatest of our physicians. A surgeon uses listerine, or some other expensive preparation, and takes all the well-known precautions and care which form a portion of modern antiseptic surgery; the results are good, and forthwith he sounds the praises of the proprietary disinfectant he has employed. Whereas if he had ordered an extemporaneous mixture, the results probably would have been better; or if he had substituted a little carbolized oil, or even alcohol and water, for the disinfectant, the results would have been as good. If the surgeon would make a scientific test of the antiseptic or antibacterial properties of the proprietary disinfectant, he would probably never himself use it, much less sign a certificate.

Exactly where this thing is going to end it is somewhat difficult to see. Like many other evils, it contains within itself the germ of its own destruction. It has already made the medical profession a laughing-stock among those who use the doctors to pull chestnuts out of the fire. It is, perhaps, not too much to hope that in a few years the people will generally recognize the folly of the profession, and the true worthlessness of these medical certificates will be so generally known as to deprive them of their force.

Meanwhile, we would advise those of our readers who desire to keep their own garments unspotted, and who dislike being made a tool of designing men, to refuse absolutely to sign any certificate of any proprietary medicine. Such signature does its writer no

possible good in any way; it does the community no good at all. The only useful purpose it can serve is to enrich a man who is only a shade above the ordinary patent-nostrium vender. It may afflict and torment an already long- and much-suffering community. Cannot the average doctor get enough of manhood about him to say No even to a commercial traveller or bland sample-distributor?

#### YELLOWSTONE PARK.

OUR readers will remember that in our last issue we corrected some inaccuracies in our previous statements in regard to the chemical work of the United States Geological Survey. At that time we had not been able to get exact information; but through the courtesy of Dr. A. C. Peale, of the Survey, we are now able to make what the French call an "inspired statement."

Dr. F. A. Gooch spent the field season of 1884 in the Yellowstone National Park as a member of Mr. Arnold Hague's Yellowstone Division of the United States Geological Survey. Waters were collected from all the more important geysers, hot springs, and rivers of the Park, and were carefully selected with reference not only to their geological significance but also to the interest taken in them by the general public. Many of those forwarded to Washington were concentrated solutions, obtained by the evaporation of large quantities of the natural waters at the place where collected. From the end of the field season of 1884 until Dr. Gooch's appointment to the chair of Chemistry at Yale College, in July, 1885, work was carried on by him at the laboratory of the Survey in Washington, with the assistance of Mr. J. E. Whitfield, and a series of forty analyses has been completed, the results of which will be of great interest to geologists, chemists, physicians, and all interested in thermal waters. Analyses have been made of waters from the following geysers, viz.:

In the *Upper Basin*,—Splendid, Grotto, Beehive, Grand, Geauter's, and Old Faithful.

In the *Lower Basin*,—Fountain and Great Fountain.

In the *Norris Basin*,—Pearl and Fearless.

In the *Midway Basin*,—Excelsior.

Waters from the following springs are also included in the list, viz.: Artemesia, Bench, Hillside, Hygeia, Coral, Schamkessel, Cleopatra, Orange, Terrace, Soda Butte, Chrome, and Ink-Pot. The waters are of remarkable

complexity, and the results of the analyses are important, both from a practical and scientific point of view.

The fact that all the waters of the region contain arsenic in quite appreciable quantity is important from a medical stand-point.

#### PROFESSIONAL SECRECY.

THE question of professional secrecy has recently cropped up at Washington in rather a novel form.

Dr. A. Y. P. Garnett recently gave a certificate of disability to an employé of the Pension Bureau. For some reason the head of the Department demanded from Dr. Garnett a specific statement as to the ailment of the patient, which Dr. Garnett refused to give. An appeal was then taken to Secretary Lamar, who sustained the doctor. It is very curious to note the different legislation which exists in the various States in regard to this matter. In France, and we believe on the Continent generally, the secrets of the consulting-room are held by law to be inviolable. In New York the doctor cannot be forced by the Court to reveal any of the statements of his patients to him, although, if the consent of the patient is given in the court-room, the doctor is capable of acting as a witness. In this State—Pennsylvania—the law is silent upon the subject, leaving the doctor subject to the common statutes.

We suppose the time will come when in this and other States the professional secrecy will be protected.

#### Reports on Therapeutic Progress.

##### ON THE ANTAGONISM OF MORPHINE AND ATROPINE FROM A CLINICAL AND EXPERIMENTAL POINT OF VIEW.

LENHARTZ, of Leipzig, ventilated the question of the antagonism of atropine and morphine before the recent German Congress. In three cases observed by the speaker no such antagonism was evinced. The numerous cases of recovery after large and even enormous doses of morphine, without the aid of atropine, as well as the high doses of atropine usually thought indicated, speak against the antagonistic theory. Johnston (Shanghai) is a warm advocate of the doctrine. The explanation of the failures of the atropine exhibition after poisoning with

morphine is, in Lenhartz's opinion, far from being satisfactory. Exhaustion and convulsions cannot be accepted as the causes of death, and the latter are much more frequent in his opinion (22.7 per cent.) than usually believed. Only in one-third of all cases does death take place here. It is, besides, singular that even minimal doses, such as  $\frac{1}{4}$  to 1 mg., are supposed to have wrought a cure. From the very extreme limits of the dosation of the antidote, we can justly deduce the uncertainty of its indication. Johnston advises the exhibition of atropine in every grave case, even in presence of a weak, irregular pulse. Wood thinks the condition of the respiration ought to determine whether or not atropine should be given, while Binz positively condemns its exhibition in a small, weak pulse. Of one hundred and thirty-two cases of poisoning with morphine observed by Lenhartz, he treated fifty-nine with atropine, and lost twenty-eight per cent., while in the seventy-three cases treated on a different plan only fifteen per cent. died. He believes that atropine is directly injurious in morphine-poisoning. Binz recommended atropine solely on the ground of experimental researches; but it must be remembered that Binz produced merely sleep and never a grave intoxication in the animals experimented upon. Consequently Binz's results are not transferable to the field of therapeutics. Binz gave only 0.029 grm. to 0.05 grm. morphine per kilo.; Lenhartz saw recovery after 0.13 grm. to 0.28 grm. morphine. Animals in which a deeper intoxication had been induced did not perish through reduction of arterial pressure or the deteriorated respiration, but through the exhaustion of the nervous centres, resulting from the numerous convulsive and tetanic paroxysms. In eight instances the speaker exhibited atropine without producing the slightest effect; the animals died just as soon as before. Hence he opposes the practice of treating cases of morphine-poisoning with atropine.

The subject is sufficiently interesting to give space also to the discussion subsequent to the reading of Lenhartz's paper.

Freimuth (Danzig) reported a case of a simultaneous intoxication with morphine and atropine which recovered, and feels, therefore, justified in believing in the existence of a physiological antagonism between morphine and atropine.

L. Lewin (Berlin) defends the experiments of Binz. Even those opposed to the doctrine of antagonism, he said, admit the favorable

influence of atropine upon the damaged respiration. The clinical cases reported upon by Lenhartz have no value in Lewin's estimation. We cannot expect infallible recovery after the exhibition of an antidote, on account of the great diversity of the conditions of an intoxication.

Lenhartz concludes as follows :

1. Atropine appears to raise the arterial pressure in cases of poisoning with morphine only in some cases and only for a short time.

2. Binz recommends small doses of atropine.

3. An effective antidote should not only improve the condition of the patient but also remove the cause of death ; hence atropine is no reliable antidote to morphine.

4. Washing out of the stomach in cases of acute intoxication with morphine should be the first and principal remedial resort.

#### SULPHATE OF SPARTEINE.

HANS VOIGT, working in Nothnagel's clinic, has come to the following conclusions respecting the therapeutical action of sulphate of sparteine. In small doses the salt increases the efficiency of the cardiac contractions and raises the arterial pressure. The number of heart-beats is always increased. These effects are observed within an hour of the administration of the drug, and continue for twenty-four hours. The author recommends the suspension of the administration of the drug for some days, but it may be given for a week without risk. The remedy does not always regulate the rhythm of the heart-beats. Its action on the respiration is variable. Diuresis appears to take place in proportion to the improvement of the cardiac action. A beneficial sedative action is often observed. Headache, vertigo, malaise, and other objectionable symptoms were but rarely met with as the result of the administration of small doses. The dose employed has been from 1 to 4 milligrammes ( $\frac{1}{1000}$  to  $\frac{4}{1000}$  gr.). It will be remembered that in Sée's hands much larger doses, 5 to 20 centigrammes ( $\frac{5}{100}$  to 3 gr.), were tolerated without cumulative or other objectionable effects.—*Lancet*, September 4, 1886.

#### HYDRASTIS CANADENSIS.

DR. WOLTERING, of Münster, confirms, in a paper published in the *Allgemeine Medicinische Central-Zeitung*, No. 47, 1886, the favorable results obtained with *hydrastis canadensis* by Fellner and other therapeutists of note.

The styptic virtues of the drug, especially in uterine fibromyomata, are very pronounced. Thus, Woltering saw cessation of the hemorrhages in three cases of fibromyoma with a uterus-length of 9 and 8 ctm. In one of the cases the uterus-length had at the end of one year decreased 2 ctm. True, besides the drug, the patient had had the benefit of long-continued self-tamponage and warm washes. The remedy was ordered in pill form on account of its unpleasant taste. Ten grammes of the fluid extract can conveniently be evaporated down to about three grammes of a dry extract, furnishing an excellent pill mass. Woltering orders usually as follows :

R Extr. hydras. canad. sicci, 6.00;  
(To be prepared from fluid extr., 20.00.)  
Extr. secal. corn.,  
Ferri redacti, aa 3.00. M.  
F. fil., No. 120.

S.—Two to five pills every three to four hours.

Of course morphine, aloes, or any other indicated remedy could be incorporated with this styptic. The above pills are taken readily and well borne, especially when taken during or after the meal. Woltering claims that neither wine, aromatics, nor liquorice cover the taste of *hydrastis canadensis* sufficiently.

In simple hemorrhagic endometritis the remedy renders also excellent service. In profuse bleeding from the lungs and stomach, however, a tablespoonful of oil of turpentine appears to be preferable.

#### THE TREATMENT OF EXCESSIVE SALIVATION DURING PREGNANCY.

Owing to the ordinary insignificance of this ailment, few medical works contain a lengthened account of it. DR. Y. SCHRAMM, however, had the opportunity, in the autumn of 1885, of observing a very severe case, and he has published some notes of it in a Scandinavian journal. Numerous remedies were employed with very little effect, for at first he imagined the salivation to be due to chronic mercurialization ; but, later, he discovered that the patient was pregnant, and that pregnancy was the cause of the condition. Neither the iodide of potassium recommended by Le Maestre nor Von Ebstein's atropine treatment had any effect. Galvanizing the sympathetic also exercised only a very slight effect. Galvanizing the cervical sympathetic was resorted to with no perceptible result. Dr. Schramm then tried subcutaneous injections of pilocarpine

(as recommended by Von Labbe and Daveyeux). After seven injections of pilocarpine chloride, 0.01 gramme ( $\frac{1}{100}$  gr.) per dose, there was a diminution of the daily quantity of saliva, as well as improvement in the general health of the patient. The excessive secretion, however, could not be entirely stopped. Bromide of potassium was tried, which acted quickly in the reduction of the flow; and Dr. Schramm prefers bromide of potassium to all other drugs, as it is harmless during pregnancy, and yet exercises a distinct effect on the salivary nerves, and on the origin of the facial nerve in the medulla oblongata, and also on the secretory filaments of the sympathetic. Professor Fleck made a chemical examination of the saliva, and found that ptyalin was absent.—*Brit. Med. Journ.*, September 25, 1886.

*THE SURGERY OF THE PANCREAS, AS BASED UPON EXPERIMENTS AND CLINICAL RESEARCHES.*

DR. SENN continues his elaborate study of the surgery of the pancreas in the October number of *The American Journal of the Medical Sciences*. In connection with the subject of wounds of the pancreas, he strenuously maintains that complete extirpation of the head of the pancreas with the common duct is never justifiable, and that operations upon this portion of the gland for injury or disease, for the present at least, must be limited to partial excision of the head, with preservation of the common duct.

He finds that cirrhosis or chronic interstitial pancreatitis sometimes produces stenosis of the bile-duct or the pancreatic duct, and that, when the obstruction is followed by retention of the secretions, an operation becomes always necessary in biliary retention, which should be treated by establishing a new outlet for the bile into the duodenum, while the formation of an external pancreatic fistula in cases of cyst of the pancreas becomes necessary only when the presence of the swelling in itself has become a sufficient source of pain and discomfort to warrant treatment by abdominal section.

In pancreatic abscess he holds that a positive diagnosis of the presence and precise location of the abscess is only possible by resorting to explorative laparotomy, and that this should be always resorted to when the history of the case and the symptoms point to a probable diagnosis. The abscess found and located by abdominal section should be removed by partial extirpation of the pan-

creas when it is endopancratic and located near the splenic end of the pancreas. When extirpation is impossible, or when it is located in the head of the pancreas or on the anterior surface of the pancreas, it should be treated by the formation of an anterior abdominal fistula; when located behind the pancreas, by through drainage, or lumbar drainage performed through the abdominal cavity.

The propriety of surgical treatment of pathological hemorrhage of the pancreas should only be entertained when the accident takes place in consequence of circumscribed, benign, pathological conditions, which in themselves do not jeopardize the life of the patient, and which admit of measures for arresting hemorrhage by direct treatment. Operative interference should therefore be limited to hemorrhagic cysts of the pancreas. In well-defined cases belonging to this group, it would be justifiable to resort to abdominal section as the only means of arresting fatal hemorrhage, by direct ligation of the bleeding points or by removing such localized portions of diseased tissue from which the hemorrhage has taken place.

*A THERAPEUTIC SUGGESTION IN WHOOPING-COUGH.*

DR. KOHLMETZ having passed through an epidemic of whooping cough, felt called upon to offer his therapeutic experience to the *Deutsche Medicinal Zeitung*, which published his communication on June 14, 1886.

The author dwells upon numerous remedies which he had tried without obtaining the slightest benefit. Among others, Kohlmetz mentions salicylic acid, which he applied to the nares in a number of cases, but soon abandoned on account of the inconvenience arising from this medication to the little patients. Quinine, given internally (according to the method of Dr. Sauerhering, of Stettin), gave likewise unsatisfactory results. Kohlmetz then tried the use of quinine in another form, which proved so eminently efficient that this mode of treatment deserves to be remembered by the practitioner. A solution of quinine is injected forcibly into the mouth, as far back as possible, against the posterior wall of the pharynx. To accomplish this end the tongue of a small child is well depressed by the mother with a suitable object, and a large child is made to pronounce the letter "a." The author declines to discuss whether the gratifying effects of quinine thus applied are due to its narcotic or antimycotic action. It

is certain, however, that the internal administration of the drug is not followed by such an improvement as is witnessed after this local application. Under this medication Kohlmetz noted in a great number of cases the whooping-cough to considerably diminish in three days, or, at the latest, in eight days. In the few instances in which the remedy was by the parents pronounced to be useless, Kohlmetz invariably learned that they, through motives of pity, had omitted the injections. In the majority of instances this procedure is not only well borne by the patient, but also openly asked for from the doctor. Kohlmetz's formula is as follows :

R Quinæ sulph., ʒi;  
Acid. sulph., fʒss;  
Aquæ dest., fʒvi. M.  
S.—As directed.

During the first three days one syringe-ful is to be injected every two hours, and in the following four days every three hours. In very small children the quantity of injected quinine is to be correspondingly small.

Kohlmetz asks for his treatment further trials from other physicians in order to confirm his personal experience.

#### MANAGEMENT OF THE THIRD STAGE OF LABOR.

DR. A. R. FISHER, assistant in the obstetric clinic of Professor Slavianski, in Kharkoff, has made a large number of observations with the view of determining the relative advantages in the third stage of labor of Credé's system of gentle manipulation or massage of the uterus, and the method of forcible expression of the placenta by powerful compression of the uterus. His statistics point decidedly in favor of the former method. In four hundred and ninety-three cases where Credé's method was employed, post-partum hemorrhage occurred twenty-five times, while in one hundred and eighty-three cases where expression was resorted to, it also occurred twenty-five times,—that is to say, the hemorrhage cases were five per cent. with Credé's method, and thirteen per cent. with the expression method. Again, the retention of pieces of membrane occurred less frequently with the former than with the latter mode of treatment, the percentage of cases in which this occurred being 5.7 and 7.4 respectively. The relative proportions of the occurrence of pyrexia, by which was understood any rise above 38° C., the temperature being taken

three times daily, were 38.3° per cent. and 46.4 per cent., and the cases in which puerperal complications supervened were also fewer after Credé's method than after the more violent procedure, being respectively five per cent. and nine per cent. A diagram is given with the author's paper, which is published in the *Russkaya Meditsina* of August 10, showing that the process of the involution of the uterus is perceptibly quicker, at all events during the first week, in cases where Credé's method has been used, than in those where the placenta has been expressed. Dr. Fisher concludes with a general eulogy of Credé's method, as being the most rational and successful plan of treating the third stage of labor, and withal so simple that every doctor, and indeed every properly instructed midwife, should practise it habitually.—*Lancet*, September 18, 1886.

#### PERNICIOUS ANÆMIA AND BOTHRIO-CEPHALUS LATUS.

DR. R. RUNEBERG, of Helsingfors, speaking at the Berlin Congress (*Wiener Med. Blätter*, September 30, 1886) about the relations existing between pernicious anæmia and intestinal parasites, remarked that he had found bothriocephalus latus to have been the cause of numerous cases of pernicious anæmia observed in Finland. After removal of the worm, the affection, previously apparently incurable, disappeared spontaneously. Of nineteen cases of pernicious anæmia treated at the University Clinics of Helsingfors, Runeberg could trace twelve to the presence of the parasite. From 1878 to 1883—when the anthelmintic medication was introduced at the clinics—Runeberg lost nine cases of pernicious anæmia, while after that period of nineteen cases treated only one died. Runeberg advances the opinion that even other intestinal parasites, which were hitherto regarded as harmless, could produce similar results. Reyher has confirmed the observations of Runeberg, and published a pertinent paper some time ago in the *Deutsche Archiv für Kl. Med.*\*

#### THE TREATMENT OF PARONYCHIA.

DR. SELLDEN writes in the *Eira* that he has for years made a special study of this subject. The greater number of his patients

\* It is interesting to learn that Runeberg met with a good deal of opposition regarding this exposition of the etiological factors of pernicious anæmia.

have been miners, smiths, machine laborers, servants, and others whose fingers are exposed to injury. The disease commences in the subcutaneous tissue and spreads to the periosteum. There are differences of opinion as to the varieties of this disease, some authors asserting that there are four, others that there are only two,—the deep and superficial inflammation. Dr. Sellden, after a series of trials, found the following method most efficacious in the treatment of paronychia. When the patient will consent to an incision, the finger, after it has been opened, is instantly plunged in a tumblerful of hot water, which is then allowed to cool till it is nearly lukewarm. Half a teaspoonful of arnica is poured in, and a teaspoonful of the usual ten per cent. solution of potassium is added. This mixture is highly anæsthetic; the finger is held in it for from fifteen to thirty minutes, when the "bad matter" comes out. This expression is very characteristic of the phenomenon. The blood and pus exude in a thin stream about the size of a knitting-needle, which forms circles in the alkaline liquid, and finally settles in a thick mass at the bottom of the glass. Fifteen minutes or half an hour after the finger is dried it is rubbed with vaseline ointment containing ten per cent. of sulphide of potassium. The finger is then immediately enveloped in a poultice which continues warm till the next finger-bath, and thus hastens the cure. These finger-baths are taken from two to four times daily, and the wound is covered during the earlier days with sulphur ointment, and later with a boracic ointment. The finger is then bound up with a wadding compress and a bandage. Carbolic acid may be used in the finger-bath, but Dr. Sellden gives the preference to arnica, which he finds particularly useful in all sorts of injuries.—*Lancet*, August 28, 1886.

#### NOTE ON THE PATHOLOGY AND TREATMENT OF FEVER.

DR. FINKLER, discussing the subject of fever at the Berlin Congress, said that the modern views regarding regulation of heat and infection, and the great number of recently introduced antipyretics, justify a discussion of the origin and treatment of fever at the present time. We must admit that in fever an increased production of heat takes place, and that this is referable to a disturbance of the nerve-centres presiding over the regulation of heat. In other words, Finkler regards fever as a neurosis, and believes to have proven his assumption in Pflüger's (Bonn)

laboratory. Fever is at the same time, in Finkler's opinion, a reaction, and, moreover, a salutary one.

In accordance with this view, the treatment of fever is to be a palliative one. It is safe to assert that the combination of baths and internal antithermic medication is the most successful plan of treating fever.

#### LANOLIN IN BLEPHARITIS MARGINALIS.

DR. J. HERBERT CLAIBORNE states in the *Virginia Medical Monthly* for October, 1886, that recently he has been making extensive experimentation with lanolin in blepharitis marginalis.

At first it was combined with the yellow oxide of mercury, in the proportion of two grains of the yellow oxide to one ounce of the excipient. Some of the patients complained of its stinging considerably on application, and one patient who had a corneal infiltration in addition to blepharitis, stated that on putting a little between the lids, the pain was quite severe, and lasted some time. It was then prescribed pure for this patient, and in this form no pain or stinging followed its application. Two crops of hordeoma were developed under its use in one case, though the same patient had already had styes during the application of warm water. At the time that the styes appeared under the use of the lanolin no warm applications were being made. There was no visible improvement in any case, either combined with the yellow oxide or alone, and the eyelashes were invariably matted and stuck together by the salve, which seemed to cling quite closely.

There was no *uniform* complaint of stinging. Of two patients, one would almost invariably answer in the affirmative, the other in the negative.

From the above observations, the author concludes that the use of lanolin in blepharitis marginalis is without good effect, and, as long as we possess cosmoline, vaseline, and other excipients, its use is not to be advised.

#### TREATMENT OF DIPHTHERITIC ANGINA.

DR. H. ROGER and PROF. PETER, of Paris, give, in *Les Nouveaux Remèdes* of August 1, 1886, the following therapeutic hints in diphtheritic angina: In the benign form give in the beginning an ipecac emetic (3 to 12 grains of powdered ipecac in an ounce of the syrup of ipecac in tablespoonful doses) every

five minutes, until emesis is produced. Apply locally twice a day lime-water, or a solution of borax or alum, or, finally, lemon-juice. In grave cases repeat the emetic once or twice, apply four to eight times daily saturated lime-water, and touch the fauces with a solution of caustic soda (caustic soda and glycerin), or with a solution of nitrate of silver (nitrate of silver, 15 grains; water, 1 ounce). In the former case the patient ought to rinse the mouth with vinegar and water; in the second case, with salt water. In both light and severe cases tonics and supporting nutriment (bouillons, beef-tea, and milk) should be freely given.

During convalescence the authors advise change of air, continuance of the supporting alimentation, and wine of cinchona. In remaining diphtheritic paralysis the electric current is to be resorted to.\*

#### SUCTION OF THE MALE URETERS.

Before attempting to excise a kidney for disease it is obviously of the highest importance to ascertain the working capacity of the opposite gland, for upon the power possessed by the latter of bearing the double burden depends the advisability of the proposed nephrectomy. The only method in which data as to this point can be obtained is by collecting the secretion directly from the supposed healthy kidney without admixture of urine from the diseased organ. This may be accomplished by the use of an instrument for tapping the ureters described by MR. FENWICK in the *Lancet*, September 18, 1886. The principle of its action is a slight suction force, which is exerted upon the ureteral orifice by means of a catheter and a small india-rubber ball. Notwithstanding the normal bladder seldom or never thoroughly contracts, the smooth muscle-wall relaxes sluggishly after its expulsive effort is over. This relaxation, at the same time that it produces a partial vacuum, diminishes the sphincteric contraction of the ureteral orifices, and any urine which may collect in those passages is partially propelled by the *vis a tergo* of the muscle of the ureters, and partially sucked by gravity and this negative pressure into the bladder. The aspirator consists of a small elastic ball and an oval glass bottle, which can be fixed to the end of a specially curved catheter, which latter is furnished with an

elongated laterally placed eye. There are two catheters, one for each ureter. The bladder is first emptied and the catheter introduced. When it has fully entered it is rotated over, and at the same time steadied by the finger and thumb to the right or the left, according as the right or the left ureter is to be engaged. The laterally placed eye will now be exactly over the ureteral orifice, for the angle of the catheter is the same as the normal angle which the outer side of the trigone builds with the long axis of the urethra. Pressure of the right hand upon the elastic ball empties it of its air, and its stem is then affixed to the end of the catheter and the ball gradually released; the air in the catheter is correspondingly exhausted, and the ureteral orifice is sucked into the eye of the catheter, where it can be maintained by careful management of the ball or by continual counter-pressure of the finger in the rectum. In ten minutes sufficient urine will have collected in the catheter, for it rarely enters the glass bottle, to admit of examination. Mr. Fenwick states that whilst this mode of procedure is not infallible, it has rendered him great assistance in determining the health or disease of one kidney in cases where an operation for the removal of the other has been proposed.

#### ARE LUPUS AND TUBERCULOSIS IDENTICAL?

Our readers are aware that within the last two years the claim has been advanced that lupus is no disease of itself, as hitherto believed, but is, pathogenetically speaking, nothing but a tuberculosis of the skin. The acceptance of this view, which, we must admit, has been a rather general one, naturally was productive of radical changes in the treatment of lupus.

It is hence a matter of no small interest that at the recent Berlin Congress this view was declared to be erroneous by DR. SCHWIMMER, of Budapest. Let us briefly review the interesting discussion which subsequently arose, and in which men of wide reputation, such as Doutrelepont, Lewin, Lassar, Neisser, and Kaposi participated.

We follow the account given by the *Deutsche Medicinal Zeitung* of September 30, 1886:

Dr. Schwimmer holds that the proofs advanced in favor of the alleged identity of lupus and tuberculosis were too few and unsubstantial to overthrow the clinical evidences which he could present that the two diseases were non-identical.

\* Henoch has in diphtheritic paralysis employed injections of strychnine with signal success.

The affection known commonly as tuberculosis of the skin is an extraordinarily rare one, while lupus itself occurs frequently. Among two thousand four hundred patients Schwimmer found ninety cases of lupus, but only five cases of pronounced tuberculosis of the skin. The clinical diagnosis in the latter affection is based on the bacterial proofs. In all of these five cases there was a rapid disintegration of the nodes. Besides, it is found that this affection invariably proceeds from the mucous membranes, while lupus appears on the epidermis, away from the mucous membranes, which, as a rule, this affection does not implicate. True, there have been observed cases of lupus on mucous membranes, but their number was very limited, and, besides, it is questionable whether the diagnosis was a correct one. Then the impression produced by the lupoid affection upon the general system is also to be taken into consideration. Tuberculosis, on the other hand, is a general disease, therefore it is not remarkable that lupoid patients sometimes become also tubercular. Hence we can look upon tuberculosis in a lupoid patient as a matter of mere coincidence. The author detailed two cases in which the clinical history went far in showing that the skin-affection present was lupus, and that the coexisting tuberculosis was an additional acquisition, having no relation with the lupus. Among ninety lupus patients Schwimmer found sixty-eight per cent. constitutionally untainted; in fifteen per cent. only he found a hereditary element. These facts speak against any etiological relation of the two diseases. Besides, it is at least singular that this relation, if actually existing, should not have been observed sooner. Schwimmer knows thirty-three cases of lupus, of which fifteen have for the last twelve years been under his observation, and of which not a single case showed the slightest symptoms of tuberculosis. As a last support of his view, Schwimmer advances the bacterial fact entering into the question. Many observers allege that in lupus but few, and but rarely, tubercle-bacilli are found. It is to be remembered that the tubercle-bacilli have a great resemblance to those found in lepra, both as far as form and chemical reaction go. Schwimmer shares the view of Prof. Babes, that the differentiation of the single bacillus is a matter of utmost difficulty.

Hence Schwimmer cannot, for all the reasons stated, be induced to look upon lupus as an affection either identical with or predisposing to tuberculosis.

As could be expected, Schwimmer's assertions met with a good deal of opposition from all quarters.

Doutrelepoint (of Bonn) overthrew one of the evidences advanced by Schwimmer, viz., that fifteen lupoid patients had for twelve years shown no signs of tuberculosis, by remarking that tubercular processes do not take a uniform course. There are, he said, chronic tubercular inflammations of the knee, which proceed benignly, and others which take an opposite course. Similarly, a general tuberculosis need not be necessarily fatal, but may remain localized in one region for many years.

In forty cases of lupus the presence of the tubercle-bacillus was distinctly made out. Koch cultivated the lupus bacilli in sixteen generations, and found no differences between tubercle- and lupus-bacilli. Lassar, Lewinski, and Lewin, all of Berlin, equally opposed Schwimmer. Kaposi, of Vienna, alone upheld the latter's view. His remarks were introduced by what appeared an especial hit against the bacteriological school. "If the gentlemen," said the Viennese authority, "have microscopical evidences of the identity of lupus and tuberculosis, we cannot help that. But above all, the clinical features of an affection must be considered, for we are practitioners and not biologists. Otherwise we will be led towards false diagnoses."

Resuming, Schwimmer remarked he knew that he could hope for but few supporters of his views, and that all the opposing arguments heard could not induce him to abandon the former.

#### THE USE OF FRESH MILK IN THE TREATMENT OF ACUTE ARSENICAL POISONING.

DR. JOSEPH JONES reports in the *Virginia Medical Monthly* for October, 1886, the notes of three cases of acute arsenical poisoning in which fresh milk given in large quantities proved of great value. The first of these cases consisted of an entire family,—father, mother, four children, and a young woman,—who were poisoned by arsenious acid thrown into a pot of soup. In these cases the excitation of vomiting and the use of large and repeated doses of fresh milk, followed by rest and milk and lime-water, resulted in the recovery of the seven individuals. In the second case, Dr. Jones was summoned to see a family, of whom he found the father lying dead on the floor of the front parlor, while the wife, son, and four servants were suffering from violent

vomiting and cramps. Investigation showed that white arsenic, which had been purchased to destroy vermin and rats, had been used by accident instead of white sugar in the preparation of pastry. The free use of fresh milk and milk and lime-water resulted in the recovery of the remaining victims. A third series consisted of a family who had been poisoned by arsenious acid ground up with the coffee. Here also Dr. Jones administered large quantities of fresh milk, followed by ipecac and warm water. Profuse and repeated vomiting was thus excited, and the stomach was thus washed out with effusions of ipecac and warm milk. As soon as the nausea had ceased the bowels were opened with castor oil. Here also all the patients recovered. Dr. Jones thinks that the milk acts by diluting the poison, enclosing it in its coagula, sheathing the inflamed surface of the mucous membrane, and when the system is capable of absorption and digestion, acting as an aliment of the greatest value.

#### DEEP INTRA-MUSCULAR INJECTIONS OF MERCURY IN SYPHILIS.

We abstract from the *Separat Abdruck aus der Allgemein. Wien. Med. Zeitung*, 1886, Nos. 32-34, the following conclusions of Dr. SCHADECK (of Kiew) concerning the advantages of deep intra-muscular injections of mercury in syphilis :

1. The injection is easily and quickly executed, and is less painful than the ordinary hypodermic injection.
2. Abscesses are never formed.
3. Coagulations, nodes, and indurations do not occur.
4. The metal is quickly and completely absorbed.

As to the technique of these injections but little skill and experience is required. A canula about three inches long is fixed on a Lewin or Luer syringe, and the needle quickly and deeply pushed into the upper or middle portion of the gluteal region in an almost vertical direction. Then the syringe is emptied under an even pressure, the point of entrance pressed by the fingers for a few seconds, and then closed by adhesive plaster.

#### A NEW TÆNIAFUGE.

DR. NUMA CAMPI calls attention in *Il Raccontatore Medico* (*Buffalo Med. Journal*, October, 1886) to the use of thymic acid, or thymol,

in the treatment of tape-worm. This substance is derived from one of the *labiata*, or thyme, which is common throughout France and Southern Italy. The plant contains a volatile substance and liquid essence called thymine, which is isomeric with turpentine, which is also a tæniafuge. It is doubtless to this volatile substance that thymol owes its anthelmintic properties, although the tannin and a bitter principle are of importance. Thymic acid, or thymol, when perfectly pure, resembles camphor, but is much more transparent, and has a glassy appearance.

It is very slightly soluble in water, but can be readily dissolved in alcohol, in ether, and in alkaline solutions. It has an acrid, warm, somewhat persistent bitter taste, and the odor of thyme.

We know but little of its biological effects. Lewin, a few years ago, claimed that it had valuable germicidal and antiseptic properties, and was four times more powerful for those purposes than carbolic acid. Bucholtz has recently made a comparative study of its germicidal properties, and finds that a solution of 1 part to 2000 will prevent the growth of bacteria, being surpassed only by bichloride of mercury, while benzoin, carbolic, salicylic, and boric acids, creosote, the sulphates of quinine, copper, and zinc, and alcohol are all inferior in their antiseptic powers. The action of thymol, moreover, is not limited to micro-organisms, but affects the higher animals and man. Lewin discovered that frogs placed in weak solutions of thymol became insensible, and lost the power of reflex action to mechanical and chemical excitation, while the electrical irritability of the muscles and nerves remained intact. Leucocytes are rapidly attacked by thymol and lose their motility. From the description of the properties of thymol it is not difficult to conceive that it may be usefully employed in the treatment of tape-worm, especially since the experiments of Federici have shown that it is very effective for the destruction of the *Anchylostoma duoænalis*,—the parasite which produces the terrible infirmity called Gottardo's disease, or miners' anæmia. But, in order to succeed with a remedy, it is not enough to know its physiological action, we must also know how to administer it ; posology is undoubtedly the most important and the most delicate part of the practice of medicine. This simple truth, so generally recognized by medical writers, must be particularly regarded in the use of anthelmintics, the effectiveness of which depends so largely on the mode of administration.

Dr. Vanni, in the first case of *tænia* treated by thymol, gave 3 grammes (gr. xlv) in divided doses through the day, and 20 grammes (3v) of castor oil at night, but succeeded in obtaining only five or six segments of the worm. On the following day, however, he administered 6 grammes (3iss) of thymol, divided into twelve doses, to be taken every fifteen minutes, and at the end of the third hour the entire worm, including the head, was expelled.

Dr. Campi adopted the following method with his first case: In the evening he ordered 20 grammes (3v) of castor oil to be taken fasting; in the morning he prescribed 8 grammes (3ii) of thymol, divided into twelve doses, one to be taken every quarter of an hour; twenty minutes after the last dose had been swallowed, another 20 grammes (3v) of castor oil were taken. A few minutes after a *tania medio-canellata* three and a half metres in length was evacuated, the head being dead.

It is very important during the administration of the thymic acid to give the patient some cordial and stimulant; cognac and rum will be found suitable. Thymol is very depressing, according to the experiments of Husemann, and this will explain its action on the nervous system. Even with small doses the pulse becomes small and frequent, the respiratory movements slow, and the temperature is lowered. These effects, however, are easily and promptly counteracted by the use of stimulants.

Dr. Campi also calls attention to another fact. Husemann and Lewin say that thymol should be administered in small doses. On account of its caustic action, they claim that there is danger of producing digestive disturbances and gastro-enteritis. They recommended two or three teaspoonfuls of a one-half per cent. solution during the day. While it is true that we can never be too prudent in the practice of medicine, these doses are too fearfully homœopathic, when we consider that 8 grammes of thymic acid may be given in two hours and a half without producing the least gastro-intestinal disturbance.

The number of remedies recommended prove that none are reliable. The *tæniafuges* have left the physician and gone to the druggist, who sells his infallible vermifuges as he does his hair-restorers. We have only to ask any old practitioner about the use of anthelmintics to learn that this class of remedies is exceedingly unreliable. Most of these remedies, moreover, produce grave gastro-intestinal disturbances, and we are not surprised that Bamberger questioned which had done mankind

most harm, the tape-worms or the *tæniafuges*. Dr. Campi recommends to the profession the use of thymic acid as a *tæniafuge*,—

1. Because this remedy, with the exception of a depressing effect, easily counteracted, produces no disturbance of the stomach or intestines.

2. On account of the rapidity and simplicity of its action compared with other remedies, which require *courses of treatment*, divided into three periods,—the preparatory, the expulsive, and the consecutive.

3. On account of the advantages it offers of being both a *tæniacide* and a *tæniafuge*.

4. Because in case of an error of diagnosis the remedy would produce an efficient purgation and disinfection of the alimentary canal.

5. Because it is reasonable to suppose that since thymic acid succeeds in expelling the *tania medio-canellata*, the worm which above all others resists the action of anthelmintics, the same remedy will be of service in expelling all other varieties of flat worms.

6. Because we have, as yet, always been successful with the use of thymic acid, and have probably found a real specific, which, up to the present, did not exist:

#### GOITRE TREATED BY CARBOLIC ACID.

DR. O. E. HAVEN states in the *Weekly Medical Review*, September 11, 1886, that he has met with a large number of cases of goitre in the public clinics in Chicago, all of which have been materially benefited, and almost all cured by the injection of 20 or 30 minims of a five per cent. solution of carbolic acid once or twice each week into the substance of the gland itself.

To do this thoroughly the needle of the hypodermic syringe is inserted one-half to one inch into the gland, and then the injection is made. Little or no pain is experienced, but only a feeling of dizziness, of which all the patients complain, and which passes away in a very few minutes. Usually this injection causes a contraction and a hardening of the connective tissue of the tumor and a gradual lessening of the blood-supply, and in the course of eight or ten weeks a complete disappearance. Out of the one hundred and fifty or two hundred cases treated in this manner, there were only two cases where any inflammation and feverish symptoms appeared, and in these cases they only lasted a day or two. The treatment is simple, almost entirely painless, as the smallest needle of the

hypodermic syringe can be used and is entirely effective. No other treatment can show such uniformly successful results.

#### A SPECIFIC FOR CONSUMPTION.

The long-searched-for infallible drug against consumption has at last been found.

We abstract the following from the *Der Fortschritt*, Geneva, September 20, 1886:

M. NAUDIN, member of the French National Institution, writes to the *Journal d'Hygiène* that *mutisia viciæfolia* cures consumption promptly and thoroughly. This statement is based on the experience of Dr. Sacc, who has been living for many years in Cochabamba, and succeeded in obtaining the stated plant—which grows in Bolivia, and is jealously guarded and kept secret by the natives—by trickery, flattery, and great presents. The plant enjoys the enviable reputation of curing phthisis and every affection of the respiratory apparatus. Dr. Sacc claims to have frequently found occasion to witness the verification of these statements regarding the plant, and does not doubt for a moment but this plant will in the shortest time acquire great celebrity. If these claims of Dr. Sacc are true, *mutisia viciæfolia* will become the greatest benefactor of mankind.

Detailed knowledge regarding this plant is as yet totally wanting. Mr. Naudin received thirty seeds of the plant, collected from about two thousand flowers, from Dr. Sacc. These seeds were planted in the Jardin des Plantes and in Algiers, and we will no doubt soon hear more about the plant. More important for the moment is the news that Dr. Sacc has sent to the Hospital for Consumptives at London and to various hospitals in Paris large quantities of an extract prepared from the plant. Thus the results will probably soon be rendered public, and we all trust that for the sake of suffering humanity these results will not fall short of his expectations.

#### THE ALTERNATIVES TO CRANIOTOMY.

From a paper with the above title, read by DR. ROBERT BARNES before the British Medical Association at its recent meeting (*British Medical Journal*, October 2, 1886), the author draws the following conclusions:

1. The legitimate aspiration and tendency of science is to eliminate craniotomy on the living and viable child from obstetric practice.

2. The advance of hygienic rule, the improvements in the forceps, in turning, in the induction of labor, and in obstetrics generally, have materially curtailed the field within which craniotomy can be justifiable.

3. In the most extreme degrees of pelvic distortion, where delivery *per vias naturales* can only be effected with doubtful success to the mother, Porro's operation is the legitimate alternative for craniotomy, it being understood that the opportunity of inducing abortion has gone by.

4. In less advanced degrees of pelvic contraction, but still incompatible with the delivery of a living child *per vias naturales*, the opportunity of inducing abortion having gone by, but in which craniotomy would effect delivery with strong presumption of safety to the mother, the Cæsarian section may be a proper alternative for craniotomy. This is the most debatable point.

5. In the minor degrees of contraction, say from three inches to three and a half or three and three-quarters inches, the opportunity of inducing labor having gone by, the far greater safety to the mother obtained by craniotomy, and the prospect of living children in future pregnancies by inducing labor, make craniotomy the proper course to adopt.

6. In other emergencies than deformity, as in obstructed labor from ovarian tumors, the alternative to craniotomy is to remove the tumor.

7. In cases of immovable tumors, Porro's operation is the proper alternative.

8. In rupture of the uterus, the child being delivered or not, Porro's operation is the proper alternative. There the interests of mother and child coincide.

9. In cases of disease or tumors of the uterus obstructing delivery, Porro's operation is the proper alternative.

10. In atresia of the cervix or vagina, Cæsarian section or craniotomy may be necessary; but incisions and gradual dilatation will more frequently be the proper alternatives.

11. When obstruction is due to hydrocephalus or dropsy in the child, embryotomy or tapping is indicated. When the child is dead, embryotomy is indicated, and decollation when the child is impacted and turning is hazardous.

12. In convulsions and hemorrhages, the proper alternatives for craniotomy are found in the more scientific methods of conducting labor under these complications.

Lastly, but the dream of Tyler Smith, the abolition of craniotomy will be fully realized

only when hygiene shall have triumphed over disease and deformity.

#### CHIONANTHUS VIRGINICA.

In *Les Nouveaux Remèdes* of August 18, 1886, we find a few descriptive remarks about *Chionanthus virginica*,—called in France "snow-tree," on account of its beautiful white flowers,—from which we condense the principal pharmacological points.

Medicinally, the bark of the root alone is employed in form of a fluid extract; saponine, discovered by Dr. Justice, probably represents the active principle of the bark.

The fluid extract is usually employed in the dose of  $\frac{1}{2}$  to 1 drachm, and is given two to three times daily for the sake of its aperient, diuretic, and alterative virtues. The drug is, besides, believed to act as a cholagogue, and to be of considerable value in jaundice. DR. J. A. HENNING, as stated in the THERAPEUTIC GAZETTE, indeed, regards the fluid extract of *chionanthus virginica* as one of the most eligible remedies in that affection. Although exercising a weak stimulating influence on the liver, Henning advocates its exhibition in cases of congestion of the portal vein. The drug is at the same time supposed to act as a stimulant to the lymphatic system, and to favor both diuresis and diaphoresis. In torpidity of the liver, Henning employs the drug, associated with podophyllin or leptandrin, as follows:

R Extr. of *chionanthus*,  $\mathfrak{f}\mathfrak{z}\mathfrak{i}$ ;  
Podophyllin,  $\mathfrak{f}\mathfrak{z}\mathfrak{i}$ ;  
Acet. of potassium,  $\mathfrak{f}\mathfrak{z}\mathfrak{ss}$ ;  
Water,  $\mathfrak{f}\mathfrak{z}\mathfrak{i}\mathfrak{v}$ . M.

S.—One teaspoonful every three or four hours.

The author adds that this treatment has never failed in cases of jaundice.

#### CURARE IN EPILEPSY.

In *La France Médicale* of September 14, 1886, we find a discussion of the therapeutic worth of curare in epilepsy which contains some noteworthy points.

BOURNEVILLE and BRICON, in a paper to the *Archiv de Neurologie* for March, April, and May, 1886, published their experiences with curare in epilepsy.

They commence by reciting the recorded experiences of numerous French physicians. Thus, Thiercelin (1861) obtained good results as long as the drug was continued. Bénédic

(1866) found it to diminish the severity and lessen the frequency of the attacks. Runge (1879) obtained numerous cures by curare. Mundt (1866) and Voisin (1867), however, obtained no appreciable results.

Bourneville and Bricon having made sure that their curare was good, and by experiment having found the proper dose for a dog, decided upon giving to the human being a dose calculated in proportion to the weight of the individual as compared with that of a dog, giving an adult weighing seventy-five kilogrammes a dose of curare of 15 cg. ( $2\frac{1}{2}$  grains). The solution given hypodermically was an eight per cent. solution. They treated thirty-three patients, including adults and children. The treatment was continued in some cases for more than six months, with the following results: One patient alone was said to be cured, one was distinctly benefited, and the third has a lessening of the severity of the convulsions.

The conclusion that the authors draw from their practice is that curare is practically useless in the treatment of epilepsy.

#### THE PATHOLOGICAL ACTION OF CORROSIVE SUBLIMATE

According to the Paris correspondent of the *British Medical Journal* (October 9, 1886), since corrosive sublimate (mercuric chloride) has been so generally used in surgery, and especially in obstetric practice, the attention of medical men has been attracted to the various intestinal lesions which have fallen under their notice. It has been asserted that mercuric chloride can produce deep lesions in the large intestines. Complex clinical facts may be interpreted in different ways, and have, therefore, not furnished convincing proofs of this assertion. Some authors suppose that, in cases of parturition where the sublimate has been used, the visceral lesions are due to the septic condition existing in the patient, and that the sublimate is not to blame. Experimental data, especially those obtained by Prévost's experiments, described in the *Revue Médicale de la Suisse Romande*, 1882, p. 553, indicate that visceral lesions often result from the effect of corrosive sublimate. Similar lesions to those observed in patients were experimentally provoked in animals; ecchymosis and hemorrhage, but neither gangrene nor ulceration were observed. MM. CHARRIN and ROGER used an aqueous solution of corrosive sublimate at 1 per 1000, and 1 per 4000,

which was injected under the skin or into the veins; this last method required smaller doses. After injecting 2 milligrammes under the skin of a guinea-pig weighing five hundred grammes, several ulcerated areas were observed; the injection of 5 milligrammes given in the course of eighteen days, or 3 milligrammes in six days, was powerless. These animals, experimented on by MM. Charrin and Roger, did not present during life any important symptoms of intestinal lesion; they grew thinner, had albuminuria, but rarely diarrhoea, and never intestinal hemorrhage. When the dose of mercuric chloride was weak, the animals did not succumb to it; they were killed at successive periods, in order to follow the course of the lesions. It was observed that the morbid appearances were localized in the large intestines, and especially in the ascending colon and cæcum; sometimes the ileo-cæcal valve and the terminal portion of the ileum were attacked. The earliest lesion consisted of small spots of hemorrhage dotted about on the intestinal mucous membrane, the peritoneum, the omentum, the outer surface of the kidneys, and especially the tissue of the lung. At a later stage these spots appeared as small ecchymoses, forming lines parallel to the axis of the intestines, varying in length from three to four centimetres. Later on, these ecchymoses became more extended, and the central portions sloughed away. A black eschar was thus formed, which gradually fell off and left an ulcerated spot. The contiguous portion of peritoneum sometimes showed signs of inflammation. Intestinal perforation has never been observed by these investigators. Thus the principal lesion which occurs after free administration of corrosive sublimate is apparently intestinal hemorrhage, which slightly tumefies the intestinal mucous membrane, and thus disables it as a factor in the process of nutrition. This hypothesis was verified by microscopical examination, which revealed the presence of spots of hemorrhage in the areolar tissue. The mucous membranes became detached and sphacelous without any glandular change taking place, as might be supposed would result from the elimination of the poison. These facts in experimental physiology applied to human patients indicate that a dose of 24 centigrammes of corrosive sublimate is necessary to produce intestinal ulceration in a man of sixty kilogrammes; but the conclusion is not applicable unless the sublimate be given in hypodermic or venous injections. It

remains also to be proved whether human susceptibility to the influence of this substance is the same as that of the lower animals; some clinical facts suggest that smaller doses of corrosive sublimate act on the human subject and provoke intestinal lesions. Nevertheless, MM. Charin and Roger do not consider that the possibility of these accidents ought to be urged as a reason for proscribing the use of corrosive sublimate as an antiseptic agent.

#### THE TREATMENT OF DIABETES WITH PEPSIN.

In the *Indian Medical Gazette* for August, 1886, there is published a paper by the late SURGEON-MAJOR E. B. GARDNER as to the value of pepsin in the treatment of diabetes mellitus. About twenty-five years ago he commenced to prescribe it, and believes that he has obtained more advantage from its use than from any other single drug, although it should be combined with the standard remedies for this affection, and the well-known rules regarding special diet should be observed. He thinks that its use permits of some relaxation of the strict diet which it is impossible to continue if the disease is prolonged.

He reports a case in which, although not entirely cured, the sugar in the urine was reduced to one-third the quantity it was when he first came under treatment, while the patient was able to freely eat starchy and saccharine substances with comparative immunity, again an improvement over his previous condition, where before the slightest indulgence in sweet substances produced immediate and a large increase in the sugar, with attendant intense thirst. During the course of this treatment a cataract operation was performed on his right eye, and resulted in a perfect cure.

He administered 5 grains of pepsin three times a day. Its continuation for six weeks reduced the quantity of urine passed from thirteen pounds eight ounces to five pounds daily.

#### THE TREATMENT OF CHRONIC GONORRHOEA IN THE MALE.

DR. O. D. BALL, in a paper read before the Medical Society of the County of Albany, N. Y. (*Albany Medical Annals*, June, 1886), takes exception to the statement made by Otis that all cases of gleet are dependent

upon strictures, either of large or small calibre. Dr. Ball is thoroughly satisfied that a fair proportion of these cases have no stricture, at least none that will resist the passage of a sound the normal size of the individual's urethra. Of course where strictures are to be found they are to be treated, and the full calibre of the urethra restored before any other means for checking the discharge can be resorted to. Of all the various methods proposed to accomplish this Dr. Ball prefers incision for very many reasons, of which the greatest is the saving of time that it allows. In the method which Dr. Ball recommends for treating chronic gonorrhœa, the recognition of the diseased portion of the canal is a matter of considerable importance. This, according to Dr. Ball, can be determined by the character of the discharges quite as well as by a sound in a sensitive urethra. In a general way Dr. Ball states that we may say that the disease is mainly anterior to the bulb when the discharge is a thick creamy mucus; when of a thin or viscid character it comes from the prostatic portion mainly. Having determined the locality of the inflammation as nearly as may be, Dr. Ball employs an ointment of oxide of zinc applied directly to the diseased membrane, using an olive-pointed bougie for carrying the ointment. The author has employed this method of treatment in fifteen cases, ten of which had contracted the disease six months or more before treatment, and in all cure was obtained. The average treatment of the cases was a little over four weeks. The longest in any one case which was under treatment was eight weeks; the shortest was ten days, except one case, who never saw any discharge after the first application was made. The formula which he employs is as follows: Zinc oxide, 3 drachms; lard, 3 drachms; simple cerate, 2 drachms. The method of using this ointment, which will adhere nicely to the bougie and yet be soft enough to apply itself to the urethral membrane, is to fill the constricted portion of the bougie out evenly and as smoothly as possible with the full calibre of the instrument, which may be lubricated with vaseline if the parts are sensitive. The bougie should be carried at once to the prostatic portion of the urethra as rapidly as possible, and then, after rotating it in both directions, it should be slightly withdrawn and then pushed back again, treating the remaining portion of the urethra in the same way. The patient should always empty his bladder previous to the application, and should be instructed to refrain from doing so again

as long as possible. The application should be made at least twice a day.

#### GYMNOCALDUS CANADENSIS.

We abstract the following note about this drug from the September issue of *La France Médicale*:

The seed of *Gymnocaldus canadensis*, which is also known by the name of Kentucky coffee-bean, has the reputation of being a powerful toxic agent, resembling Calabar bean, with which it is allied. The watery extract of the drug modifies the sensibility considerably. Five minutes after a hypodermic injection of this preparation the frogs were insensible, and would not respond to irritation. With a moderate dose the sensibility of the conjunctiva remained, and on increasing the dose the anæsthesia became complete; perception and sensation became abolished. Motor troubles, consisting of general convulsive movements, the rigidity and subsequent paralysis of the muscles being complete, resulted. These phenomena had their origin in the central nervous system. The drug, besides, lessens the activity of the cardiac nerves, and acts as a stimulant to the pneumogastric nerve. The cardiac pulsations are diminished by one-half; and, finally, there is a lowering of the arterial tension.

#### THE USE OF SOME NEWER REMEDIES IN DISEASES OF THE UPPER AIR- PASSAGES.

At a recent meeting of the American Laryngological Association Dr. E. L. SHURLEY (*New York Med. Journ.*, September 11, 1886) read an elaborate report as to the results which he had obtained by the employment of a large number of some of the newer alkaloids and glucosides when used topically in diseases of the upper air-passages. As Dr. Shurley's experience has been very large his results must naturally be of proportionate value, and we therefore think that we are doing our readers a service by presenting a full abstract of his conclusions.

*Aconitine*.—Dr. Shurley has records of twenty-five cases in which it was used either in the form of a spray or pigment. Two were cases of laryngeal phthisis; seven of chronic pharyngitis,—in five of which there existed acute exacerbation; eight of acute pharyngo-laryngitis; three of chronic follicular amygdalitis; three of chronic laryngitis; and two of pharyngeal neuralgia. The amount used each time varied from  $\frac{1}{16}$  to

$\frac{1}{160}$  of a grain. In each instance there occurred in a few minutes the well-known physiological effects of tingling of the tongue and feeling of choking and numbness, to which were superadded, when applied in the nasal fossæ, lachrymation, with sneezing and vertigo. On two occasions these local symptoms were very severe and distressing to witness.

Only once did he observe a marked effect on the pulse immediately after the application. With a small dose— $\frac{1}{160}$  grain—these symptoms passed away in about two hours; with the larger doses from four to six hours elapsed before the patient became comfortable.

As to the local effect, in every case there arose in a very short time, almost immediately, an active hyperæmia. Even in the case of phthisis the pale color was deepened to a vivid rose, or a near approach to it. The ulterior effect was, in the acute cases, to cut short the course of local inflammation; in the cases of chronic pharyngitis, etc., there was no permanent effect, the cases of pharyngeal neuralgia—severe paroxysmal pain on one or other side of the pharynx—occurring respectively in a pregnant woman and in a woman suffering with supposed chronic inflammation of the ovary. The application of the pigment with a brush twice daily produced immediate and marked relief, although not a cure.

From these observations, therefore, he thinks that this agent as a local application was of little benefit, except in a few particular cases, while its very unpleasant effect upon the sensations of the patient was entirely out of proportion to its therapeutic value.

*Agaricin* (a glucoside from the *Boletus larius*).—From the good effects in the abatement of nocturnal sweating which he has observed from the administration of this agent, Dr. Shurley was led to use it topically in a few cases of chronic nasal and pharyngeal disease, but, as he did not observe any physical or therapeutic effect, he has nothing to report at present.

*Arbor Vitæ*.—On account of its reputed efficacy in causing the disappearance of syphilitic warts, Dr. Shurley was led to use this drug as an application to intra-laryngeal papillomata. In one case, that of a boy 14 years of age, who was suffering with a progressive growth of these tumors on the vocal cords and ventricular bands, it certainly acted remarkably well. Only one of the growths—the largest—was removed by the forceps, the others disappearing under the use of a spray of the aqueous extract, applied

once or twice daily, for a period of about three months.

In another case, in an adult, where there were five papillomata in the region of the anterior commissure of the vocal cords, this remedy only partially succeeded, the forceps having been resorted to for the larger ones. The treatment, however, seemed to prevent their renewed growth.

In still another case, one of cystic tumor of the right vocal cord, the *arbor vitæ* has had no effect whatever, unless, perhaps, to suppress catarrhal inflammation.

He has also used *arbor vitæ* in the local treatment of some cases of chronic laryngitis with benefit.

In preparing the fluid extract for spray, to render it unirritating it will be necessary to drive off nearly all the alcohol by means of heat, boiling it down to a syrupy consistence, and afterwards add water to the amount of one-third to one-half of the amount distilled off, then filter.

*Ammonium Glycyrrhizate*.—As a spray he has obtained no particular effects. Dr. Shurley prescribed it for a large number of cases of acute and chronic bronchial catarrh, in doses ranging between 2 and 5 grains. In the chronic cases it seemed inferior to ammonium chloride and ammonium iodide, but in the acute uncomplicated cases it has proved itself a valuable expectorant.

*Cannabine Tannate* (from *Cannabis indica*).—On account of the difficulty of making a solution of this substance, Dr. Shurley used it mostly in the form of powder mixed with starch, or in the form of an ointment with vaseline. He has used it in about fifty different cases, sixteen of which he has notes of, and a majority of these were cases of nasal or naso-pharyngeal disease. It possesses astringent properties, and is also a decided local stimulant. When applied undiluted to the nasal mucous membrane it causes considerable irritation, which lasts for a period of two to four hours, producing lachrymation and swelling of the turbinated mucous membrane. But when applied diluted with starch in the proportion of two to five grains to the drachm or with vaseline in like proportion, it has, as a rule, no such irritation, but a decided astringent, and afterwards soothing effect. It has proved a valuable agent, according to his experience, as a substitute for tannic acid, which latter he has ceased to use in the nasal chambers on account of its irritating effect; with children suffering from swelling of the nasal mucous membrane, either acute or sub-

acute, it will prove an excellent and efficient application, especially when mixed with vaseline.

*Cadmium Sulphate*.—This salt, which has been highly extolled as an astringent, is not superior to sulphate or chloride of zinc. Dr. Shurley used it as a spray and pigment in about thirty cases, in the proportion of from one-half to five grains to the ounce, and has noted no particularly beneficial result over zinc sulphate and chloride or silver nitrate, excepting in one case where the unpleasant results following the application of any solution of silver nitrate forbade its use. The cadmium certainly acted well, and seemed to bring about the desired result.

*Cotoin* (the active principle of coto bark).—Although there is not much literature upon this subject, it is reputed to be a good remedy for chronic diarrhoea and the diarrhoea of phthisis. Dr. Shurley administered it in two cases of diarrhoea of phthisis, but without signal success. He used it locally in about twenty cases of nasal and pharyngeal disease, twelve of which he has notes of. It is a powerful irritant to the nasal and pharyngeal mucous membrane—both healthy and diseased—and leaves no reactionary effect. Its best effects are obtained in cases of atrophic nasal and pharyngeal catarrh, and, when diluted in starch or sugar in the proportion of one part to three or four of excipient, it is, according to Dr. Shurley, quite equal if not superior to any other application—excepting galvanism.

*Coniine Hydrochlorate* (a salt of the alkaloid of *Conium maculatum*).—From the well-known selective action of conium on the muscular system and sympathetic nerve, one would suppose that this alkaloid—readily diffusible as it is—would act signally as a corrective in those local disorders of the throat and larynx characterized either by co-ordinate or ordinate spasm, etc.

Dr. Shurley has notes of ten cases representing various spasmodic actions of a pathological nature of the pharynx and larynx, one of which was an hysterical laryngeal cough, and one a local chorea, in which he applied this agent repeatedly in progressive doses (both by means of spray and pigment) without any sensible result in modifying the diseased action. He is therefore disposed to regard it as wanting in value for a local medicament.

*Daturine* (an alkaloid from *Datura stramonium*).—From the known value of stramonium as an anti-spasmodic, and its especial utility in the relief of spasmodic asthma, he

was led to give this alkaloid a thorough trial as a topical remedy in affections of this sort.

He has notes of twenty-three cases subjected to experiment, as follows: 1, bronchial asthma; 1, spasmodic asthma; 2, periodic laryngeal congestion; 3, hay-fever; 1, chronic bronchitis (bronchorrhoea); 3, hysterical pharyngeal catarrh; 5, influenza; 1, laryngismus (with ovarian disease); 2, chronic naso-pharyngeal catarrh; 2, acute coryza; 2, chronic laryngitis.

The dose varied from  $\frac{1}{100}$  to  $\frac{1}{50}$  of a grain, and in some of the cases was repeated two, three, or four times a day; in each case, when the dose was large enough or frequently enough repeated, there appeared to the patient sooner or later the characteristic sensation of dryness of the fauces, etc. The patients with asthma were not sensibly affected by the treatment; two of those with hay-fever were very much benefited by the applications if repeated often enough (it was used in the form of spray), but the trouble was not arrested; three of those with influenza were decidedly relieved by three applications daily of a spray ( $\frac{1}{100}$  of a grain), while the two others were not at all relieved. The neurotic cases were only relieved by a diminution of secretion, which, however, lasted but a few hours, necessitating a repetition of its use.

*Ethyl Bromide*.—This has been used almost entirely as an inhalation for the relief of cough. Dr. Shurley tried it in a large number of cases; it is not quite so efficacious as chloroform, but there is much less general anæsthesia from its continued use, and it leaves no unpleasant after-effects. He thinks, therefore, that it is deserving of more extended use for the relief of severe dry cough and spasmodic asthma.

*Hyoscyine*.—The hydrobromate is the salt which has been used. He has been unable to note any marked effect, proximate or remote, from the local use of this salt,—excepting in a few cases there arose a sensation of dryness which passed off in about an hour.

It produces no apparent change in the condition of the mucous membrane to which it is applied. The doses used varied from  $\frac{1}{100}$  to  $\frac{1}{50}$  of a grain.

*Iodol*.—Dr. Shurley used iodol in a few cases of ulceration of the mucous membrane, both specific and ordinary, and observed that it has nothing like the power to arrest the ulcerative process which iodoform possesses, although he cannot say but that slow improvement and healing followed its use. It

is sincerely to be hoped that this substance will prove to be a capable substitute for iodoform, because it is free from odor and causes no bad taste. He always applied it by insufflation.

*Papain* (papaw juice).—In one case of diphtheria he applied the fresh juice, and in six other cases it was used in the form of a glycerole,—either one-half or two-thirds strength; but no solvent action was observed on the exudate in any case. He adds that this was the experience of two other practitioners in his city, who also tried the remedy in cases of diphtheria. Therefore, so far as this limited experience goes, it has utterly failed to sustain its reputation as a remedy for the relief of real diphtheria.

*Muscarine Sulphate* (alkaloid of *Agaricus muscarius*).—Very little is known about this drug, but it is said to resemble in its physiological action that of physostigmine. Dr. Shurley applied it in doses of from  $\frac{1}{8}$  to  $\frac{1}{16}$  of a grain in twelve cases characterized by dryness of fauces and larynx, without any result excepting in two. One of these patients presented signs of great dryness of the fauces, and lack of buccal and salivary secretion, accompanying general nervous prostration; and the other had "dry catarrh" of the pharynx and larynx. In both of these cases a spray, repeated three or four times a day, seemed to afford great relief. The immediate effect was a pleasant tingling sensation, soon followed by comfortable heat and more secretion. No effect on the pupil was observed. In the other cases no immediate or remote effects, either objective or subjective, could be observed.

*Physostigmine Salicylate*.—This was thoroughly tried in a number of instances, of which he has six recorded. In but one instance did it produce any physiological action, or in any obvious way relieve the pathological condition of the parts. This case was that of a delicate young man who had from time to time suffered from spasmodic stricture of the lower pharynx and œsophagus; he experienced almost immediate relief from an application of  $\frac{1}{16}$  of a grain, which lasted about six hours, when another application became necessary. At the end of forty-eight hours the attack ceased. Nothing which the writer had ever used locally in this man's case had acted so well as this agent in cutting short the course of the attacks.

*Pilocarpine Hydrochloride*.—Dr. Shurley has five recorded cases of pharyngeal catarrh characterized by a sensation of dryness and

consequent distress in which he has tried this remedy, in doses varying from  $\frac{1}{16}$  to  $\frac{1}{4}$  of a grain, but without any positive result.

*Piscidin* (a glucoside from *Piscidia erythrina*).—Dr. Shurley has nine cases recorded in which this was used either as spray or pigment, in doses ranging from  $\frac{1}{16}$  to  $\frac{1}{4}$  of a grain. In only one instance could there be observed any proximate or remote effect, and that was a case of phthisis characterized by a very persistent and aggravated sensation of tickling referred to the pharynx. In this subject the application of a pigment in the proportion of  $\frac{1}{16}$  of a grain to the drachm, every two or four hours, seemed to relieve the trouble in two days.

*Resorcin*.—Although attention was first called to this agent in 1860,—when it was presented as a supposed substitute for carbolic acid,—yet medical literature does not show that it has been at all extensively used until very recently. Dr. Shurley used it considerably during the past year, and believes it to be an important addition to the pharmacopœia. It is practically odorless and tasteless, while it is soluble in water; it is very feebly caustic, and, although a weak, still an efficient antiseptic. He has the records of thirteen cases in detail in which resorcin was used with good effect. Three were secondary syphilitic ulceration; one, tertiary; six, ozæna,—of which one was an aggravated case where the turbinated bones had disappeared; one, eczematous lupus of nose and pharynx; one, ulcerating and eczematous lupus; and one, typical herpetic pharyngitis.

The case of ulcerating lupus needs some additional remarks, inasmuch as it was a peculiar one; the subject, a child 9 years old, had been suffering for nine months; first with an obstruction of the nasal passages and an irritating discharge therefrom, followed gradually by the growth of fungous granulations in these passages and about the edges of the nares and upon the roof of the mouth (about the centre of the hard palate). When he saw her in February, 1886, there were extensive ulcerating granulations in the nasal passages and upon the surface of the roof of the mouth as well as at the margins of the nares; the nasal column was also ulcerated and its cartilage denuded. The patient's general condition was also much below par. Having anæsthetized her, he destroyed with the galvano-cautery all the fungous tissue that he could reach and applied iodoform thoroughly. The iodoform was applied for

several days, as was also resorcin (in the proportion of one to four and one to six), but the main treatment afterwards consisted of resorcin used as a spray or pigment. The galvano-cautery was applied to two small spots in the mouth once since, but otherwise the treatment has consisted of the application of resorcin (and vaseline to moisten the parts) every day, conjoined, of course, with a recuperative and tonic plan of treatment. He saw the patient last on the fifth of this month (May), and observed that she was in good health, with very little deformity about the nose, and no reappearance of the trouble excepting at a spot situated on the inside of the cartilaginous nasal column. She is still under treatment. In the cases of ozæna, especially the one with the loss of the turbinated bones, the effects of this agent, used once or twice daily, as spray, were quite prompt, and it seems remarkable. The patient was under treatment about five weeks. He saw him about two weeks ago, and he told Dr. Shurley that he was comparatively free from trouble, and had been for the last three months; he uses a douche every day (as might be expected) of salt and water. Has no pain now and no more discomfort than is usual after such a lesion. The ulcerative process is apparently checked.

*Sanguinarine Nitrate* (a salt of the alkaloid of *Sanguinaria canadensis*).—No special results follow the local use of this drug, but for internal administration in a certain class of cases it is highly useful as a stimulating expectorant. He has noticed no unpleasant effects or depression from it in doses of  $\frac{1}{16}$  to  $\frac{1}{4}$  of a grain in syrup.

#### ICE-WATER ENEMATA IN TREATMENT OF DIARRHŒA.

DR. ROBERT M. SIMON, writing in the *British Medical Journal* for October 30, 1886, states that this mode of treatment has frequently been adopted in cases of collapse occurring during diarrhœa in young children at the Birmingham General Hospital. He recommends that ice should be dissolved in water and from two to three ounces injected. In his experience, which he says has been quite extensive, the immediate effect is good in producing sleep, as is important in the collapsed condition. Subsequently the effect upon the diarrhœa is also good, and it will rarely be found necessary to repeat the enema. Dr. Simon thinks that the cold enemata act by an astringent effect on the

loaded vessels of the intestines, and so diminish the intestinal flux. It has sometimes been found to be expedient to give a few drops of brandy about the time of the injection, and perhaps internal medication should be continued. In his experience no depression or bad effect has ever resulted.

### Reviews.

NEW MEDICATIONS: By Professor Dujardin-Beaumetz. Translated by E. P. Hurd, M.D., etc. Parts I. and II. Detroit, Mich.: Geo. S. Davis, 1886.

So many new methods by so many men, new and old, crowd upon the practitioner, that he must either become a bookworm and abandon practice for reading, or, ignoring them all, allow his patients to suffer in the old-fashioned way. For such men nothing of late has appeared in print more useful than the condensed but practical and explicit work before us. Part I. contains, among others, chapters on "New Cardiac Medicaments,"—convallaria majalis, caffeine, and trinitrine,—with briefer mention of adonidine, sparteine, cactus grandiflorus, and cereus bonplandii. "New Methods of treating Stomach Diseases," which contain remarks upon gastrotomy, gastrostomy, and gastrectomy, the use of chloroform-water, carbon-disulphide-water, used in "lavage" of the stomach, forced feeding, or "gavage." Chapter iv., on "New Gastro-Intestinal Medications," treats of the application of electricity to stomach and intestines, of enteroclysm, alimentary lavements, anæsthesia by the rectum, and the treatment of hemorrhoids by hamamelis virginica. "Antiseptic Intestinal Medications" and "New Pulmonary Medications" complete the topics of Part I., while Part II. contains the pulmonary medications, treating of the mechanical means recently brought into use by the pneumatic cabinet, and by various modifications of its principles; in short, all the change in method and medicaments produced by the discovery of the bacillus tuberculosis are here studied, and the relative value of the different agents employed subjected to close scrutiny. "Antiseptic Pulmonary and Pleural Medication" forms the subject of two chapters, which are followed by "Antithermic Medicaments," new and old, by a chapter on the "New Hypnotics," chloral and paraldehyde, "On New Analgesic Medicaments," and "On Local Anæsthetics," the latter containing a close study of cocaine. The reader

can see from the above how large and important a field is covered by these two small volumes of the Physician's Leisure Library.

A MANUAL OF DIETETICS. By J. Milner Fothergill, M.D. Edin.

New York: William Wood & Co., 1886.

A really good book on dietetics would save more lives than a new work on therapeutics, but in the last few years the profession has made rapid strides towards scientific and rational feeding. The author says, "The day of dietetics has arrived," yet a careful reading of his pages will convince any one that there is, with much progress, much still to learn. We do not yet perfectly understand the intricacies of digestion, but each year we draw nearer to its sanctuary. We can now proceed on fixed principles, and at least formulate a truly scientific method of feeding. We may have to unlearn many things now considered as settled, and there is still a vast field for the explorer.

Dr. Fothergill is always an interesting writer. His style is captivating, and never more so than in the opening chapter on "The Objects of Food." Here one can see what unscientific feeding has been in the past ages of the world. In the chapter on "Forms of Food, with their Digestion," the author has embodied almost everything known on the subject, but in "Methods of Preparing Food" and "Condiments and Sauces" is contained the very rationale of cookery. "Condiments are curiously omitted from the dietary of invalids" is a sentence which deserves attention. The chapters on "Beverages" and "Stimulants" will attract alike the indulger and the abstainer, and contain a world of solid sense and carefully-digested experience. The chapters on prepared foods and artificial digestive agents will enlarge the knowledge of most readers considerably. The author expresses the wish that his knowledge of the prepared foods of the United States was as extensive as of those of Great Britain; and, *vice versa*, the medical man of average reading will find many preparations mentioned by the author by no means familiarly known to himself. Of peptonized foods the author gives a complete and satisfactory account. Following him as a guide, their use would be restricted to cases where they can be reasonably expected to be useful. He does not believe in "making a pauper of the stomach," by assisting it too soon or too long. The author gives careful directions for peptonizing milk gruel,—milk gruel soups,

jellies, and beef-tea through the use of liquor pancreaticus,—and for peptonized enemata.

In Part II. we have chapters on "Food in Infancy," "Adolescence," "Adult Life," "Old Age," in "Acute Disease," "Convalescence," "Gastric Affections," in "Struma," "Anæmia," in "Constipation and Diarrhœa," in "Phthisis," in "Chronic Heart- and Lung-Disease," in "Bright's Disease," "Diabetes," "Gout," "Neuronal Affections," in "Obesity," "Indigestion," and "Biliousness," and in some other conditions, and the work concludes with a chapter on "Food given otherwise than by the Mouth." The reader can see what a wide field is covered, and while some of the subjects are treated briefly, they are treated carefully, as is the chapter on "Food in Obesity," which covers less than four pages, yet in that space we have not only an explanation of the reasons of obesity, but a careful description and analysis of the methods of Banting and Prof. Ebstein, with the author's comments on both. The chapter on "Gout" is thoroughly practical, and its material is very largely drawn from the author's own observation. It would form useful reading for many other than medical men. The author, however, leaves out of the question any consideration of gouty dyspeptics, as he would otherwise render his "chapter more complicated than desirable," and in doing so fails to show us how ably he might struggle with the complicated problem. Leaving out the gouty dyspeptic leaves out the greater part of the difficulty, and enables him to fall back upon the time-honored advice to eschew meat,—“No gouty man can drink malt and eat meat at the same time without paying the penalty.” Of lager he speaks more favorably. Of wines, he reserves for the gouty “a poor thin wine, as the poorest claret or corresponding Italian,” while spirits with water form “the best drink beyond doubt, and help to wash the uric acid out of the tissues.” In the chapter on “Food in Diabetes,” which the author distinguishes from simple glycosuria, giving his weighty reasons for so doing,—reasons which should be read and carefully considered by those who are ready to put their patients upon the rigid diet of the diabetic upon the first detection of sugar in the urine,—in this chapter the author raises many questions concerning the necessity for rigid diet. This is a thoroughly practical question, and very ably handled. “Is it, or is it not,” he asks, “the fact that many persons fairly to be regarded as diabetics suffer much more from their diet-

ary than their malady?" In fact, he believes that during the quiescent periods of diabetes in many cases some relaxation should be allowed, and can be allowed with benefit rather than injury. In "Food in Constipation and Diarrhoea" the author says, "So long as animal broths are permitted so long will diarrhoea be intractable." Again and again, he remarks, has this been "driven like a spike" into his memory. Yet it is only a few years ago since beef-tea was the staple diet of typhoid patients, and in regard to the question of beef-tea the author is exceedingly plain and decided. In fact, the book is full of suggestions, and if not the ideal work on the subject, is the nearest to it in our knowledge, while the author's graphic style tends to fix his ideas upon the mind, and renders them far more valuable. In short, it is a work that all practitioners should read and re-read, and endeavor to use in their every-day work.

THE GENUINE WORKS OF HIPPOCRATES. Translated from the Greek, with a Preliminary Discourse and Annotations by Francis Adams, LL.D., Surgeon. Two volumes. Vol. II.

New York: William Wood & Co., 1886.

To those who cannot read Hippocrates in the original Greek, and who are tormented with a burning desire to read him anyhow, this work will commend itself. Perhaps there may be in his writings much of practical and real value, but most of it has long since been incorporated in the works of modern authors. Possibly more is found in his pages than he ever dreamed of himself. The modern method of Biblical criticism applied to ancient medical works is capable of discovering almost anything the discoverer desires. But to those intending to settle in Greece, to engage in active practice at Parnassus or Olympus, the book will be invaluable.

In looking through this second volume, we at least carry away one fact. Hippocrates has protested against the modern heresy of homœopathy in no feeble words. "It is the business of the physician," he says, "to know in the first place things similar and things dissimilar;" and in his mind the "dissimilar" was of equal importance with the "similar."

Throughout the work the annotations of the editor are copious and wonderful; especially is this so in the "aphorisms." The more sententious the aphorism the more voluminous the annotation, and they at least serve to show us what the translator imagined his author to mean.

To those who are fond of ancient lore the work will undoubtedly prove a valuable and interesting possession.

MEDICINE OF THE FUTURE; AN ADDRESS PREPARED FOR THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION IN 1885. By Austin Flint, Sr., M.D., LL.D.

New York: D. Appleton & Co., 1886.

This address, never delivered as intended, has been published by the son of the late Dr. Austin Flint from his father's manuscripts, and now speaks to a larger audience than even the British Medical Association could have afforded. It is written in a happy vein, in its author's usual style, and deals, as its title imports, with speculation as to the future progress of our art. Of course no very pertinent prophecy could be anticipated, or if it contain such, time has not yet fulfilled it, but it is well worth reading, both out of regard to the rare man who wrote it, and for the interest which gathers about such speculations from a man so actively engaged in a practice of fifty years. Some of his words are words of warning, some of encouragement and hope, and over it all is a shade of sadness at the thought that the pen that wrote it, the mind that conceived it, are both at rest, and can take no part in that future progress of which he so hopefully wrote.

THE USE OF ELECTRICITY IN THE REMOVAL OF SUPERFLUOUS HAIR, AND THE TREATMENT OF VARIOUS FACIAL BLEMISHES. By Geo. Henry Fox, M.D., etc. The "Physician's Leisure Library." Detroit, Mich.: Geo. S. Davis, 1886.

Hair tonics and restoratives which are not dyes have had their day, and here the hair-destroyer steps to the front, and immediately we are made aware of the immense number of individuals, mostly females, whose lives are rendered miserable by superfluous hair. It has struck us, since so many of these cases exist, that it may be possible that poor, blundering Nature grew these hairs where she did under the mistaken impression that they added beauty to the feminine lip, and that our Anglo-Saxon standard of feminine facial hairlessness might be a mistake. Of course, like every one else, we draw the line on chins anyway. One hardly could wish even an enemy's grandmother to have chin whiskers, and so the superfluous hair-destroyer is not in any case wholly superfluous. As a rival to the depilatory he deserves encouragement, for the depilatory takes skin and hairs and everything but bones, and can so easily be applied by the unscientific with such dire results that

the very difficulty of the electrolytic process is a point in its favor.

The complete method is given by Dr. Fox in his small but carefully-written work,—all the details, the difficulties, the failures. With the proper battery and instruments, which he minutely describes, and with a steady hand, good patience, and some practice, we imagine that most men can become successful superfluous-hair destroyers. We are waiting for the hair-planter next.

E. W. W.

**THE MODERN TREATMENT OF EAR-DISEASES.** By Samuel Sexton, M.D.  
Detroit, Mich.: Geo. S. Davis, 1886.

This book presents a classified list of over two thousand consecutive cases of ear-disease at Dr. Sexton's aural clinic, New York Eye and Ear Infirmary. It is intended to "bring into prominence the more practical features demanding treatment." "The cases have been divided, according to the anatomical location of the disease, into nine sections,—auricle, external auditory canal, drumhead, middle ear tract, complication of diseases of middle ear tract, mastoid process, important symptoms of ear-disease, neuroses, deaf-mutism." The author remarks in the introduction that a more complete classification will be found at the end of the book.

This book contains a fund of valuable information on diagnosis and treatment, not alone for the aural specialist, but still more for those members of the profession who, possessing some knowledge of aural disease, and daily meeting cases in practice, are a little at a loss at times, and while retaining the treatment in their hands, long for the more accurate knowledge of special study. There is nothing very technical or abstruse in the presentation of the cases, but they are very clearly described, very usefully classified, and in the appendix will be found a full account, well illustrated, of the methods, instruments, and formulæ used.

**HOW TO CARE FOR THE INSANE. A MANUAL FOR ATTENDANTS IN INSANE ASYLUMS.** By Wm. D. Granger, M.D., etc.

New York and London: G. P. Putnam's Sons, 1886.

The author of this little work has no new system for the management of the insane to introduce, no new theories to ventilate, but aims at supplying the intelligent attendant with a reliable and compact handbook, in which he will find directions for most emergencies and for the better conduct of his reg-

ular daily work. He gives a slight sketch of the nervous system, an outline of the generally accepted facts concerning mental diseases, and discusses insanity briefly, with its hallucinations, illusions, and delusions. The delusion, by the way, of thinking one's self a king or queen is one, according to the author, rarely met with in our free and favored land. "He does not expect such things among Americans." He probably expects his patients to imagine themselves ward politicians, rounders, and political bosses, or perhaps missing treasurers, bank defaulters, or delinquent city officials. Such are the beneficent effects of free institutions. Of moral insanity he says, "There are those who claim that the moral nature alone may be diseased."

"Many delightful friendships," he remarks, "are formed between attendants and patients." Probably those with homicidal mania form the warmest attachments, and "there is more appreciation and gratitude among the insane than there are contrary feelings;" but for all this we appreciate, we trust, the author's work, and recommend his manual as a book likely to be of use to those for whom he designed it. With how much deeper appreciation and gratitude the insane themselves would regard it we can form no estimate.

E. W. W.

**A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, EMBRACING THE ENTIRE RANGE OF SCIENTIFIC AND PRACTICAL MEDICINE AND ALLIED SCIENCE BY VARIOUS WRITERS.** Illustrated by chromolithographs and fine wood engravings. Edited by Albt. H. Buch, M.D. Vol. III.

New York: Wm. Wood & Co., 1886.

The late Dr. Austin Flint, in his "Medicine of the Future," said, "Voluminous encyclopædic works have probably had their day," and "there is reason for thinking that textbooks which assume to extend over the whole domain of medicine will soon belong to the past;" but in spite of these wise words of a wise man, we think we see a wide field still open for such books as the "Reference Handbook," by no means a "handbook" in the sense of being small and convenient. It is so elaborate, full, and complete that one almost wonders whether, equipped with its series in full, the practitioner would need anything more. Certainly, when all the learning in these volumes has been assimilated and stored away in one brain, its possessor would be well provided for. The scheme of the work is very ambitious, and its execution commensurate with its editor's intention. Its

type is excellent ; its illustrations profuse and apt ; the articles written by men of authority and learning in their special lines at least. Take its articles on the "Forceps," on "Fractures," on "Fungi," as illustrations. Nothing more complete could be desired or expected. The article on "Fungi" especially is illustrated with chromolithographs of wonderful perfection, and will prove a true boon to the mushroom-eater, causing him to have one shudder the less as he eats his dubious meal. The anatomical topics, too, are extremely well illustrated, as also the section on "Hospitals, Hygiene, and Habitations," the latter giving the most perfect description of the various appliances for house drainage that we have ever met. In short, it is a work the first complete view of which will almost of necessity raise in the beholder the passion of possession. For in these busy times, when every moment is of value, when in want of information, there should be some reliable and ready method of obtaining it, and until the world grows slow again, we imagine that just such handbooks as this will be held in a very increasing esteem. E. W. W.

### Correspondence.

---

#### LONDON.

(From our Special Correspondent.)

On the 1st of October medical life in London awoke from its pleasant autumn siesta. We are all back in town and hard at work again. Hospital practice has been resumed with fresh vigor. The medical schools are crowded with young and eager hearts, starting fresh on the course which many of their teachers would fain themselves again pursue. The societies have one after another had their opening night. It is at the societies as much as in the hospitals that a visitor among us can see the active spirits of our professional world ; and it occurs to me that those of your readers who have not yet crossed the water may be pleased to hear something about these gatherings.

The most important of our professional societies is the Medical and Chirurgical Society, which is nearly as old as the century. This is the Royal Society of Medicine in England : possessed of convenient if not imposing rooms and a very fine library, and publishing an annual volume both of "Transactions" and of "Proceedings," which are highly valued. This society is supposed to

attract the more elaborate papers produced with us,—papers that embody the results of research, of purely scientific bearing, or that do not readily fall under a clinical or a pathological heading. One hears complaints that "the Medico-Chi" is not sufficiently frequented by the younger men ; but of this more anon.

Older even than the Royal Medical and Chirurgical Society, indeed a ripe centenary, is the Medical Society of London, which, after a somewhat checkered career, has renewed its youth wonderfully within our recent memory, has built itself a handsome house, has reorganized its library, and has returned to fresh activity generally. The Medical Society is the least severely scientific of all our larger societies. It attracts many general practitioners to its meetings, and is thus a most valuable institution to the profession here, not only as being a social link between the family doctor and the consultant, the importance of which it would be difficult to exaggerate, but also because it introduces into our discussions the very kind of experience in which some of the members are comparatively wanting,—the experience of family practice. These remarks apply with even greater force to the Harveian Society, a small institution compared with those I have just mentioned, but one *par excellence* of and for the general practitioner, with a wholesome sprinkling of consultants to represent the hospital element. It is at the Medical and the Harveian that one may expect to hear real useful therapeutics discussed,—therapeutics stripped of the gloss of scientific novelty and put to the test of routine general practice.

Next to the Medico-Chirurgical in respect of scientific position come three societies which you may see regularly reported in our journals,—the Pathological, the Obstetrical, and the Clinical Societies. These are all very flourishing bodies, full of attraction to the more energetic spirits among us, publishing their respective "Transactions" every year. An evening at the Pathological is much affected by our youngest men. This is practically a society for the exhibition of specimens of morbid anatomy, with occasional discussions on subjects of pathology proper. The work of the Obstetrical Society corresponds so far with its name, but "gynæcological" would have been perhaps a more correct title. It fortunately attracts a fair number of general practitioners.

Lastly, we have the Clinical Society, which is of the most interest to your readers and myself in our present relation, inasmuch as it

was originally intended to be mainly a therapeutical society,—a society to which its members might bring for report and for discussion not only their observations but the results of their attempts at scientific treatment. It is comparatively a young institution, having seen but eighteen sessions. The Clinical was started as a kind of protest against the all-absorbing tendency of the Pathological Society. It was an attempt to bring us back to the consciousness that our business as doctors after all does not end with an attempt to lay a vast foundation of pathological science on which the medicine of the future may be surely built, but should be directed also to the relief of present suffering. You will agree with me that the following words of one of the greatest masters of modern English medicine, the late Sir Thomas Watson, which were spoken by him at the inaugural meeting of the Clinical Society, deserve to be disinterred from the first volume of the "Transactions," published in 1868 :

"The society which we are founding to-night seems to me well-calculated gradually to bring about that which, in my judgment, is the thing most needful at present among us,—I mean, more exactness of knowledge, and therefore more direct and intelligent purpose, and more successful aim, in what is really the end and object of all our labors,—the application of remedies for the cure or relief of disease. Certainly the greatest gap in the science of medicine is to be found in its final and supreme stage,—the stage of therapeutics. . . . We have attained to a great degree of certainty in the detection and discrimination of disease in the living body. We know tolerably well what it is we have to deal with ; but we do not know so well, nor anything like so well, how to deal with it. . . . To me it has been a life-long wonder, how vaguely, how ignorantly, how rashly, drugs are often prescribed. We try this ; and, not succeeding, we try that ; and baffled again, we try something else ; and it is fortunate if we do no harm in these our tryings. . . . Of therapeutics as a trustworthy science, it is certain that we have, as yet, only the expectation. The influence of drugs upon the bodily conditions of health and disease is, indeed, most real and most precious to us ; and some of them we have learned, in our contests with disease, to wield with much confidence and success."

It is wonderful how unwillingly we accept these unanswerable propositions at this moment in London. The *raison d'être* of the

Clinical Society is only too clearly illustrated by its history. It constantly tends to relapse into a society for living *versus* dead pathology. Members bring their patients there, or read their cases there, but in the whole course of an evening you may never hear a word about treatment, always excepting the surgeons, who freely avail themselves of the opportunity to publish their novelties in the way of operations. This, for example, was the programme of the opening meeting on the 8th of October : A case of congenital malformation of the heart, with a discussion on the pre-diastolic murmur ; a case of undeveloped sexual organs, with congenital defect of the tonsils ; a case of pulsating tumor of the head, with Raynaud's disease ; and further notes of a case of renal lithotomy. The truth is, that therapeutics is at a discount at this moment in England. The term "scientific therapeutics" is scouted by many here. Whilst your American journals, especially the THERAPEUTIC GAZETTE, are filled with papers of great value to the practitioner of medicine, many of our most active minds will not bend themselves in the direction of drugs. There are several reasons, as it seems to me, for this state of matters :

First, the problems of pathology are ever more attractive in such a place as London. Whether on the living subject or in the *post-mortem* room, "material"—as our German *confrères* rather irreverently call the *corpus vile* of the human frame—is ready at hand in abundance. Trained in the latest methods, our junior hospital men can quickly get together a case or a paper on a novel tumor or an anomalous eruption. It is a very different matter to undertake a laborious and faithful research on the value of a remedy, which may cost months of incessant labor, where a few imperfect observations may ruin a whole series, and where the result may after all be disappointing. Scientific therapeutics is not the kind of occupation to commend itself to us in these days of life-at-high-pressure. It is hardly necessary for me to add that the neglect of drugs has led to comparative ignorance of their action and uses, which, in turn, has begotten a widespread scepticism of pharmacology. I trust I may be forgiven for using the word "ignorance" when I explain that I refer to ignorance of the modern pharmacology of established remedies,—of the alkalies, iron, lead, antimony, opium, quinine, ergot, broom, etc. Men who have but little faith in physic do not trouble themselves to add to their ancient knowledge of these commonplace remedies,

and they are only brought into an attitude of attention when some new drug is introduced into practice. Their opinion of scientific therapeutics is founded on an estimate of the value of novelties, which are, alas, only too often of but evanescent reputation!

But we are not entirely without hope. I am reminded to-day of a quarter from which our favorite subject may look for the inauguration of a better order of things. The Harveian Oration was delivered this week on Harvey's birthday at the College of Physicians; and at this college there is a fair prospect that an effort will be made to follow the advice which their immortal Fellow left behind him,—to "search out the secrets of nature" by the revival of scientific therapeutics. Twelve months ago the then Harveian orator, Dr. Quain, lamented the decline of the healing art, and pleaded for the endowment of a therapeutical lectureship. The appeal did not fall on deaf ears. I have heard that the college has determined to apply at least part of the funds accruing to it under the Croonian trust to the endowment of an annual lectureship on some subject "in anatomy, physiology, or pathology, *with a view to the prevention, control, and cure of disease.*" You may smile at the amount of thankfulness which I express for so small a mercy as this clause extends to us; but I anticipate with confidence that this lectureship will encourage and foster that kind of practical therapeutical research in our hospitals the absence of which I have just lamented.

This letter would be incomplete without a few words about our junior societies. Within the last year or two we have had three hard-working societies on special branches of medicine started in London,—the Ophthalmological, the Dermatological, and the Neurological. These three bodies have these features common to them, that they "mean work," and that the members are more anxious to promote mutual improvement in the knowledge of the several specialties which they represent than to distinguish themselves publicly. I have little doubt they have a long and useful future before them.

#### "RHODAN."

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I take the liberty of calling your attention to a little matter which once puzzled me a good deal, and I think may some of your other readers.

On page 536 of the August number is an abstract of an article on the action of *rhodan*. I think very few will know that *rhodan soda* (of the Germans) is nothing more than our familiar sodium sulphocyanide.

WALTER MENDELSON, M.D.

No. 209 WEST 46TH ST., NEW YORK,

November 9, 1886.

#### GRINDELIA ROBUSTA AND YERBA SANTA IN BRONCHITIS.

To the Editors of the THERAPEUTIC GAZETTE:

DEAR SIR:—In looking over an old number of the THERAPEUTIC GAZETTE (November, 1885), I noticed a reference to an article I contributed to the *Medical News*, on the combination of the fluid extracts of *grindelia robusta* and *yerba santa* in bronchitis. Now, as there is a typographical error in the formula as given in your reference, and you have characterized the article as obscure, I would like to make the following explanations and correction through your valuable journal.

I have always found the following combination to produce the most salutary results in the first or pre-exudative stage of acute bronchitis, and to be especially effective in relieving the tickling, irritating cough which supervenes on assuming the recumbent position. I have used this combination for about five years in hundreds of cases with better results than I have been able to obtain from any other preparation. It is also valuable in the second stage of acute bronchitis and the chronic form of that disease; but here in our high altitude (six thousand seven hundred and thirty feet), at least, it exerts its most favorable influence in the first stage of the acute form of the disease.

R Fluidi extracti yerbæ santæ,  
Fluidi extracti grindeliæ robustæ, aa ℥i;  
Syrupi tolutariz vel simplicis, q s. ad ℥viii. M.  
Sig.—℥i or ℥ii every hour or two as needed for cough.

A more concentrated preparation than the above will cause nausea in certain cases, and not act more effectively than the weaker mixture above indicated.

Very truly yours,

E. STUVER, M.D.

RAWLINS, WYOMING TERRITORY, October 28, 1886.

#### PROPRIETARY MEDICINES.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—This question is being freely discussed by the medical profession, and the

expression generally is in opposition to their manufacture and sale, except it be under certain restrictions or regulations.

That we may be the better prepared to apply the remedy to any evil, it is oftentimes necessary to know the cause that produces the evil, and in the consideration of this subject we think it very necessary to consider the cause that has led to, and now sustains, this extensive traffic, because it is sustained by the people, and there must be a cause for their having drifted into such an expensive and injurious habit.

In this, as in many other investigations, we cannot trace out one cause, but find many influences that tend to accomplish the same end, but a few stand out prominently and exert the controlling influence in establishing and perpetuating this traffic, which, if removed, would do much to banish a business which is so pernicious to the people and against the success of the true physician.

*Polypharmacy* has probably done more than any other one thing to create a demand and perpetuate a desire for proprietary medicines. The physicians who indulge in polypharmacy to the extent that their prescriptions contain from four to twelve agents, must of necessity have volume to obtain a compound that can be endured at all, and their patrons have come to look upon a large volume as being necessary. They look for it and expect it, and if they do not receive it they feel that they have not received the worth of their money, have put a commercial value upon the medicine, instead of recognizing the professional ability, and always contrast the bill with the sized bottle received, instead of the knowledge and skill manifested in diagnosis, prescription, and cure.

*Empiricism*, or routine practice, the twin brother of ignorance and stupidity, also forms an important factor in engendering and continuing this traffic. Oftentimes we find physicians who have a routine in practice. They give pills to physic, and quinine as a tonic after the patient has been "cleaned out" by the physic, or they have become so skilled in their knowledge of disease and the action of medicines that they can treat successfully a large per cent. of cases by their favorite compounds. They have an ague compound, a cough mixture, an alterative syrup, a cholera cordial, a liver pill, etc., and every person afflicted with ague, irrespective of age, sex, or condition, is prescribed for from the same compound, and each of the mixtures are dispensed in the same general way, until their

patrons look upon them as medicine-venders, and again compare the amount of medicine received with the bill charged, and again with the amount that can be secured of the druggist for the same money, and find the amount to be greater, and therefore invest their money where they get the *largest* returns, thereby reducing the business of the physician to the plane of commercial exchange.

*Prescribing proprietary medicines*, or preparations so closely allied to them that it would require greater discriminating powers than is usually exercised to distinguish the difference.

The country is flooded with almanacs, receipt- and picture-books, containing laudatory accounts of the magic power of some "old and reliable remedy," or of some "new and wonderful discovery," that is so potent for good that many of the "eminent" physicians are prescribing it daily with marvellous success, and close with a number of certificates from the M.D.'s of the wonderful cures effected, thereby impressing the people that the practice is made up by prescribing such compounds, and again they are led to compare the amount prescribed with what they can obtain from the druggist for the same money, and estimate the curative art from a purely commercial basis.

How often do we find the physician inquiring through some medical journal the composition of some compound which he has been using, but of which he knows nothing, except it has been highly recommended, for the case in hand, and that results are not always satisfactory!

What we need to banish forever the baneful influence of proprietary medicines is a profession that will study to know the significance of certain pathological symptoms, and strive to know the actions of remedies singly, and search to know the relation of symptoms and remedies, thereby enabling them to meet certain symptoms with certain agents with as much certainty as we expect emesis after the administration of ipecac or lobelia, or catharsis after the administration of podophyllin or Epsom salts.

Prescribe singly, as far as possible, thereby learning the action of the various agents in the concentrations and attenuations, and learn what conditions can be met and relieved in the best possible manner in the least possible time with our various remedies.

Banish compounds from our shelves, and, if needed, prepare specially for the case, thereby teaching our patrons the important truth that no remedy, single or compound,

can be successfully prescribed in a "class" of cases known by a certain name, but that each case must receive its special treatment in accord with the special conditions that exist.

The American people are a dissipating people. They desire to work hard, late and early, physically and mentally, gormandize and engage in innumerable excesses, and yet be free from pain and enjoy the blessings of health; and if they do not, they hope to right all things by means of drugs, the satanic deception of which is found in the form of hypnotics in a large per cent. of the proprietary medicines, which, by their quieting influence, delude in the idea that restoration is being effected, forgetting the important truth which every physician should impress upon the minds of his patrons, that health can neither be perpetuated nor restored by means of drugs while living in open violation of the hygienic and dietetic laws governing health.

A. S. HUSTON, M.D.

PENDLETON, IND., October 29, 1886.

#### CONCERNING NOSTRUMS, ETC.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—About semi-occasionally there is a howl sent up about proprietary articles, quacks, etc. Now, let us look at the subject of nostrums from a rational standpoint.

Scarcely a day passes but what the "busy practitioner" receives circulars for some wonderful preparation designed for the relief of suffering humanity: appended to this interesting pamphlet is a list of diseases in which this discovery "may be used to advantage" (that is, to the financial advantage of the proprietors); following this list will be found recommendations from physicians, many of whom occupy professors' chairs in medical colleges. How much they receive for their endorsement we humbler representatives of the profession, of course, do not know; but one thing is sure, and that is, that students, as a rule, look at their professors as being nearly infallible, and, accepting blindly their words as medical gospel, will naturally use these nostrums composed of—what? The manufacturers alone know, and they trust to the credulity of the profession for their income; they are sharp enough to put at the end of the circular in prominent type, "*Sold only on physicians' prescriptions,*" and also send their agents around to distribute samples; then, for fear the M.D.'s vanity

will not be tickled enough, complimentary letters are written. This special mark of attention is simply another tickle under the ribs, causing an additional enlargement of the bump of "self-esteem" when we consider our importance.

The doctor "in ordinary," I am sorry to say, is not a reasoning animal, hence mental exertion is to be sedulously avoided; besides, there is Gull & Co., who manufacture remedies that will cure any human ailment: if the patient perchance die, why, "The Lord giveth, and the Lord taketh away," etc.

Now, the cause for the production of these nostrums, or "why is this thus?"

The majority of physicians talk of and prescribe for diseases as though they were entities, not pathological conditions.

The Indian supposes sickness to be the result of the presence of evil spirits, which must be exorcised. Not quite as crude, but equally as ridiculous, is the idea held by too many of our profession at the present day.

Now, let every physician, when called to see a patient, sit down and study the case before him, endeavor to discover the lesion, then do his own prescribing, using remedies whose value and composition are known and recognized, instead of the ready-made prescriptions put up by the considerate manufacturer, and whose real composition is veiled in obscurity.

Again, instead of trying to legislate against nostrums, etc., for the protection of the "dear people," let the doctor be what the name implies,—a teacher. Teach our patrons such simple hygienic laws as should be known by every one for the avoidance of the simple ills that result from their neglect. Show the public that we are not wholly selfish, and as we educate them to a right method of living, though at first it does not put as many shekels in our pockets, in the long run we will be the gainers,—for the reason that the sale of nostrums will be diminished, the respect and reputation of the doctor increased (and necessarily his practice), which should be synonymous with wealth.

Just as well legislate to make men honest as to stop the manufacture and sale of nostrums. Education alone will do the work, hence it is the duty of physicians to do their own thinking, which will of necessity compel them to fit the remedies to the patient, instead of the reverse; then will the manufacture of preparations "for physicians' use only" cease, but also the demand for those other nostrums which load the shelves

of drug-stores under the name of "Proprietary Medicines" gradually become extinct.

So long, however, as the physician, when a patient feels a little "off," tells him to go to the drug-store and get a box of "Carter's Liver Pills," "Castoria," "Winslow's Soothing Syrup," or a blood-purifier, conveying the idea, meantime, of disease as an entity, just so long will nostrums be put on the market and find a ready sale.

The profession must look among themselves for aid in abolishing this evil,—for evil it is,—not to the Legislatures of their States; for in other cases it has been pretty conclusively shown that prohibitory laws do not prohibit.

In fact, whenever the people are ready for a measure, then and only then will it be adopted, and until that time we are only "kicking against the pricks" in trying to gain legislative measures on this subject.

Now, instead of issuing a "legal boycott" on these manufacturers and their preparations, let us by study and application fit ourselves so that *we* are the best judges of what the patient needs, then give it; in this way the nuisance of nostrums will die a natural death of suffocation.

The physician should be a better judge of what is required by his patient than a man or set of men in China, Sandwich Islands, or any place, except at the bedside.

KENT O. FOLTZ, M.D.

AKRON, OHIO.

#### MEDICAL LEGISLATION.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—It is my wish to make a few suggestions to Dr. F. T. Field, of Elroy, Wisconsin, and other of the readers of the GAZETTE who do, or who think they need, the protection of legislative enactments.

They should commence by instructing the people publicly and privately concerning proprietary medicines where nothing is or can be known about mixtures when no formula is given.

Physicians should not "hide their light under a bushel," but let it *so shine* that the people will not patronize proprietary mixtures.

If they wish to do anything in bringing about favorable legislation, they will have to commence long before the primaries by first selecting a man for the place who will do your work (he should be a good worker); then have an understanding among the physicians of the State or districts to work for the men so chosen.

If they (the physicians) have tact and will work together, they can nominate any man or men they wish. If a man is nominated who is opposed to your measure, commence talking against him to some of his warmest friends. He will visit you (for he cannot afford to have any influential physician against him). You can then make your demand, and, of course, he will promise to aid you. Have him put that promise in writing for use among physicians only, and, as a reminder to the Hon. Gentleman from Juneau County, a witness or two to that signature might be useful to strengthen the case.

If you ask for a law, do not ask for one unfair or exclusive, as you would fail to obtain it, which would serve you right.

If you do not succeed the first time you try, do not become discouraged and write to the THERAPEUTIC GAZETTE complaining of your ill success, but try again at the next session.

Have your bill ready, and have it introduced, read, and referred to the Committee on "Rights and Privileges." In the mean time write a letter, urging the passage of the measure, to every member of each branch of the Legislature with whom you are acquainted, and have all of your medical friends do the same all over the State.

If each member should receive half a dozen letters and as many petitions from his constituents he would think that law was in great demand, and he would not only vote for it, but would be anxious to do so.

I had a little experience a few years ago in getting an "Anatomy Law" passed in our very conservative State. I drew the bill and had it introduced, and to my surprise it passed the House of Representatives by a large majority, and lacked but one vote of passing the Senate the first round! The next Legislature I had it introduced again, and it passed the House but failed in the Senate. The third time I sent it to the member of the House from my own county, but he returned it to me with the assurance that "*it would fail.*" I sent it to a younger member, and it was introduced, when a physician, who had been a member at each of the three sessions, had it modified and passed, and it is the law today.

Our "Medical Practice Act," passed in 1855, came in the same manner, excepting it was worked upon for twenty years before it became a law.

Legislatures are very conservative bodies. They will not make radical changes unless

the demand for them is very urgent. Usually the worst foes to anything of the kind are physicians. They are the very ignorant ones or those who "stand high in the profession," and fear they will lose their standing if the ignorant ones are legislated out of business.

Suggestively yours,

I. B. WASHBURN, M.D.

RENSSELAER, INDIANA.

## Notes and Queries.

### TREATMENT OF ACUTE AND CHRONIC NASAL CATARRH.

DR. H. MARKS, of St. Louis, writes us as follows:

"I have a very good prescription for a snuff for acute or chronic catarrh, also traumatic rhinitis and acute coryza, especially when accompanied with pain of the nasal nerve. This formula effects a cure in twelve hours. It can be used as a snuff by the patient himself or in a powder-blower.

R Cocaine hydrochl., gr. x;  
Ol. eucalyptus, gr. iii;  
Iodoform, ℥i;  
Milk sugar, ad q.s. ℥i. M.  
Ft. triturate (snuff).

Sig.—Use every two or three hours. When relieved use two or three times a day.

"Another formula which I have found of service is a modification of that recommended by Beverly Robinson, which is as follows:

R Pul. fol. belladonnæ, gr. xx;  
Cocaine muriate, gr. v;  
Ol. rosæ, gtt. i;  
Pulv. gum acaciæ, ad q.s. ℥ss. M.  
Ft. triturate (snuff).

Sig.—Use with the powder-blower for anterior and posterior nares."

### FLUID EXTRACT OF JABORANDI AS A LOCAL APPLICATION IN ECZEMA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Having used fl. ext. jaborandi in erysipelas with good results, I have given it a trial in two cases of eczema, and have been so pleased with its action that I send brief reports of cases, asking others to make trial and report.

CASE I.—Male; aged 35; American. Each spring has an attack of acute eczema. Father subject to same. Eruption in patches all over body; intense itching. Gave internally liq. ars. et hyd. et iodidi, and ordered fl. ext. jab.; applied full strength to eruption. Itch-

ing relieved after first application. Recovered in a few days.

CASE II.—Physician; aged 60; American. Chronic eczema of the forehead of many years' standing. Skin very much thickened and cracked. Said he had tried everything he could learn of, and wanted me to see what I could do. Intense itching very disagreeable when air came in contact, so that he had to keep covered with a handkerchief. Applied fl. ex. jab.; full strength caused sharp burning for a few seconds. Reported in an hour he could stand contact of the air without discomfort. Continued application for several days, two or three times a day. Skin became thin; abrasions healed. Reports that he can only feel a slight discomfort when he becomes very warm. Feels so well he neglects to apply the remedy.

I report these two cases thus briefly, hoping others may more fully try and report progress with the remedy.

Respectfully,

G. W. ROBINSON, M.D.

TRINIDAD, COLORADO.

### HELENIN.

Alant camphor ( $C_8H_{10}O$ ).

The alant root (starwort) and extract drawn from it. Helenin had enjoyed for a long time the repute for being counter-irritants, and during the last few years helenin has been introduced. It is in form of colorless, neutrally reacting needle crystals. The melting-point is at  $110^{\circ}$  C. It is almost insoluble in water, but dissolves readily in hot alcohol, ether, and fat, or ethereal oils.

The views as to the value of this remedy were and are still divided. Merck, in his circular, calls attention to the substance, because it has lately again attracted the interest of physicians, as the increased demand and numerous literary publications abundantly prove. DR. KORAB deduces from the antiseptic qualities of helenin its power of subduing tuberculosis, malaria, and catarrhal diarrhoea. According to Dr. Korab, one part has the power to protect 10,000 parts of urine from putrefaction.

Dr. Valenzuela obtained excellent results in cases of whooping-cough. Chronic bronchitis always disappeared after the use of helenin. Dr. Valenzuela points out as constant symptoms after the application of the remedy, the abatement of cough, of asthma, and of pain in the chest; a narcotic effect helenin does not produce. It acts as a tonic

on the digestive organs, so that it may even be given to consumptives suffering from severe diarrhoea.

Dose, 0.01 grm. helenin ten times a day ; of the tincture (1 to 5), three times daily, five drops.

In the department Gilette in the Hôpital Tenon at Paris there is an antiseptic dressing material used under the name "Hélénol du Dr. Korab," which very likely is a solution (alcoholic) of helenin.

#### CRYSTALLINE SALICYLATE AND SULPHATE OF PHYSOSTIGMINE.

• These preparations, which enjoy the deserved attention of the medical world, do not require a general description. Of particular interest surely is the fact, recently proved, that eserine administered in very small doses against diarrhoea produces a remarkably lessening effect, while so far it was only known that larger doses act as purgative.

The fact that very small doses of eserine reduce the pressure of the blood, and larger doses increase it, is well known. This is based simply upon a lowering and raising of the activity of the heart. In connection with the laxative effect of the eserine prescriptions, the local action of the same agent upon the bowels has to be carefully considered. The peristaltic movement would be largely increased ; the same may assume such dimensions that "cramp of the bowels" would have to be taken into consideration. Even after death this cramp continues for some time ; the contractions connected with the same compress the intestinal vessels and expel the blood, so that the secretion ceases. Thereupon rests the recommendation of this remedy against cholera, but it seems improbable that a medicine of so diverging action should find extended internal application during an epidemic.

Attention is further called by Merck in his circular to the prescription of physostigmine against intoxication, with atropin and hyoscyamine, or daturine and duboisine respectively ; dose for this purpose, 0.002 to 0.005 grm. subcutaneously. The advantage of this medicine is essentially in strengthening the contractions of the weakly throbbing heart.

In Mendel's *Centralblatt für Nervenleiden* a notice by DR. ESCHLE recently appeared, which emphasizes the efficiency of physostigmine against diarrhoea.

Dr. Eschle has used physostigmine sulph. in a one-half per cent. solution subcutaneously,

in doses of 0.001 to 0.0015 grm., and thereby stopped more or less severe diarrhoea. Larger doses (0.0025 grm.), however, show the known laxative action of physostigmine. Dr. Eschle specially recommends it in cases of dysentery, where it is important to check the bleedings which have such a weakening tendency and the albuminous defecations at least for some time.

#### SPANISH WINES.

*La Vara de Esculapio* (August 31, 1886) publishes an exhaustive leading article on the adulteration of wine in Barcelona, and gives an analysis of some "choice" ports :

Not alcohol.....	12.2 per cent.
Extractive.....	9 grammes per litre.
Ley.....	4.60 " " "
Sulphate of potassium.....	2.6 " " "
Alumina.....	0.180 " " "
Bitartrate of potassium.....	Normal.

The alcohol contained amylic spirit in large quantity. The other analyses were similar.

The named Spanish journal deserves every credit for the good work it is doing in exposing quackery and detecting adulteration.

#### GELOSINE.

According to the Paris correspondent of the *British Medical Journal*, October 9, 1886, at a recent meeting of the Société de Thérapeutique M. GUÉRIN read a paper on gelosine, a mucilaginous substance extracted from a Japanese alga, which is sold in the form of dry whitish leaves. Gelosine is an excellent base, mixing easily with all pharmaceutical substances, soluble in alcohol and water, and in acidulated or alkaline water ; it served as a medium for salts, powders, and different tinctures, and was of great utility in preparing suppositories. Gelosine gradually contracts and expels the water and medicinal substances it contains, which are thus spread over the surface of wounds or cavities in which it is placed in any form. Gelosine thus gradually regains its original volume, but can be used more than once for the purposes cited above. Gelosine, therefore, appeared to be preferable to liniments and ointments. M. Guérin showed specimens of cylinders and slabs of gelosine, containing camphor, creosote, sulphate of zinc, cocaine, tincture of belladonna, iodoform, corrosive sublimate, carbolic acid, and coal-tar. In order to use gelosine as a medium, the quan-

tity required should be immersed in its weight of hot water; the therapeutic agent is then added and incorporated. When the mixture becomes as thick as syrup, it is poured into moulds. These operations were completed in a quarter of an hour, and the expense was slight. Sterilized gelosine might be utilized in bacteriological research.

#### ANCHIETEA SALUTARIS.

The root of *Anchietea salutaris*, a violaceous plant, having a popular reputation in Brazil as a remedy in skin-diseases, has been recommended as useful in syphilis (*Chemiker Zeitung*, 1886, p. 619). The dose is 0.1 to 0.35 gm. of the powdered root daily, and the drug is also administered in the form of a syrup prepared from a tincture of the root. In consequence of the drug being used for syphilis and provoking a flow of saliva, it shares with some other substances the name of "vegetable mercury." Some years since DR. PECKOLDT called attention to the usefulness of the drug in skin-affections. He administered the powdered root, commencing with 0.35 to 0.70 gm. three times a day, and gradually increasing the dose.

The first effects are drastic, but these pass off after a day or two. Dr. Peckoldt isolated from the root-bark an alkaloid, which he considered to be the active principle, and named it "ancheitine."

#### NOTES ON SOME NEW DRUGS.

We abstract the following from *Der Fortschritt*, September 26, 1886:

1. *Ulexine* (seed of *Ulex Europæus*) furnishes an alkaloid called ulexine by Zerrard.

Physiological action: Applied to frogs the drug acts as a paralyzing agent.

Placed upon the tongue the hydrochlorate of ulexine causes anæsthesia, though to a less extent than cocaine.

2. *Cortex Cascara Amarga* (from the West Indies, from which Thompson prepared the alkaloid picramine) is said to be valuable against skin-diseases and syphilis.

3. *Jucaranda Lancifolia*.—In doses of 10 drops of the tincture and of 131 of the extract the drug is claimed as a specific against gonorrhœa and syphilis.

4. *Njimo-Wood* (of West Africa) is regarded by the natives as a remedy against gastric pains and loss of appetite. Like the coca-leaves in Peru, the njimo-wood is used as a stimulant by the negroes.

5. *Radix Aristolochia Cymbifera* is said to surpass in energy the officinal serpentaria. In Brazil, the home of the plant, the drug is regarded as a sure cure for snake-bite and typhoid fever, and is called "mil homens."

6. *Radix Coca-Coca*.—The Indians in Peru use this drug against liver-affections and muscular colds.

7. *Radix Ping-Ping*.—Prof. Möller examined this drug, and states that it is valuable in vesical troubles.

8. *Radix Tayuga*.—Stated to be of use in syphilis and skin-diseases.

9. *Semen Anda Assu*.—The oil acts like castor oil, but has the advantages of being a finer fluid and acting in smaller doses. Home, Chili.

10. *Semen Huingan*, Chili.—Used as an infusion against urinary affections.

#### LIATRIS ODORATISSIMA.

A frequent importation into the port of Hamburg during the past year has consisted of the stalks and leaves of the *Liatris odoratissima* (deer's tongue, or southern vanilla), which is said to be employed as a substitute for the more expensive tonka-bean in the scenting of snuffs. MESSRS. JEHE state that the quantity of cumarin in the drug is considerable, but it has never, in their experience, reached the amount mentioned by Wood, of two drachms to the pound.

#### EXCESSIVE SWEATING OF THE HANDS.

Excessive sweating of the hands is a source of much trouble, especially to dentists, whose hands of all things should be clean and free from the slightest odor. According to the *British Journal of Dental Science*, October 1, 1886, a mixture of salicylic acid or oxide of zinc with acacia powder will prove useful, although often boracic acid in saturated aqueous solution acts very well.

#### A NEW BITTER.

In a letter to the editor of *La Voz de Hipocrates*, DR. CRESCENCIO GARCIA recommends a Mexican plant, which is known popularly as "guachacata," as a substitute for quassia, gentian, etc. It yields a bitter principle to alcohol and boiling water. No analysis has been made of the plant, nor is its natural family named, yet the fact that it is largely used speaks evidently in favor of it and invites trials with the drug.—*Med. Press*, October 27, 1886.
